A selected group of 103 patients with uncomplicated myocardial infarction of less than 24 hours' duration were randomly assigned to two different treatments: 45 patients received quinidine sulfate orally in a dose of 0.4 g every 8 hours and 58 patients received sodium lactate placebo. The period of observation was 72 hours. Ventricular tachyarrhythmias, including ventricular tachycardia, and ventricular premature beats that were multifocal or occurred at a frequency greater than 5/min occurred in 26 of 58 patients (45 percent) receiving placebo and in 7 of 45 patients (16 percent) treated with quinidine. Quinidine effected an even more significant reduction of ventricular tachycardia; this arrhythmia was observed in 12 of 58 patients receiving placebo and in only 1 of 45 quinidine-treated patients ($P < 0.01$). Continuous 72 hour electromagnetic tape recordings showed no reduction in the frequency of isolated ventricular premature beats in the quinidine-treated group compared with the control group. Bradyarrhythmias including heart block warranted discontinuance of the trial in 6 of 45 quinidine-treated patients and 2 of 58 patients receiving placebo. There was no difference in mortality in the two groups during the 72 hour study period or during the entire period of hospitalization.

The advent of coronary care units together with the present treatment of ventricular arrhythmias is credited with reducing the mortality of patients admitted to the hospital with acute myocardial infarction.[1–4] Although the monitoring and emergency treatment facilities of coronary care units are becoming more widespread, they are not universally available. It has been stated[5] that 50 percent of patients entering the hospital with acute myocardial infarction in the United States are admitted to hospitals that have less than 200 beds and probably lack special monitoring facilities. It is attractive to consider that an oral antiarrhythmic agent administered to patients admitted to hospitals without coronary care facilities might reduce mortality from ventricular arrhythmia.

Quinidine sulfate, the prototype of antiarrhythmic agents, has been in clinical use for more than 50 years, principally for the reestablishment and maintenance of sinus rhythm after supraventricular arrhythmia. It has also been effective in the treatment of established ventricular tachycardia. Its pharmacologic action and clinical efficacy in the treatment of ventricular tachycardia naturally led to its trial in the prevention of ventricular arrhythmias, including ventricular premature beats.

Although in early studies[6–8] the use of quinidine was advocated for prevention of ventricular dysrhythmias after acute myocardial infarction, subsequent attempts to validate this approach by clinical therapeutic trials have yielded conflicting opinions. Thus, although some investigators have offered no support for such routine use of quinidine,[9–11] others[12–17] have suggested that this prophylactic approach

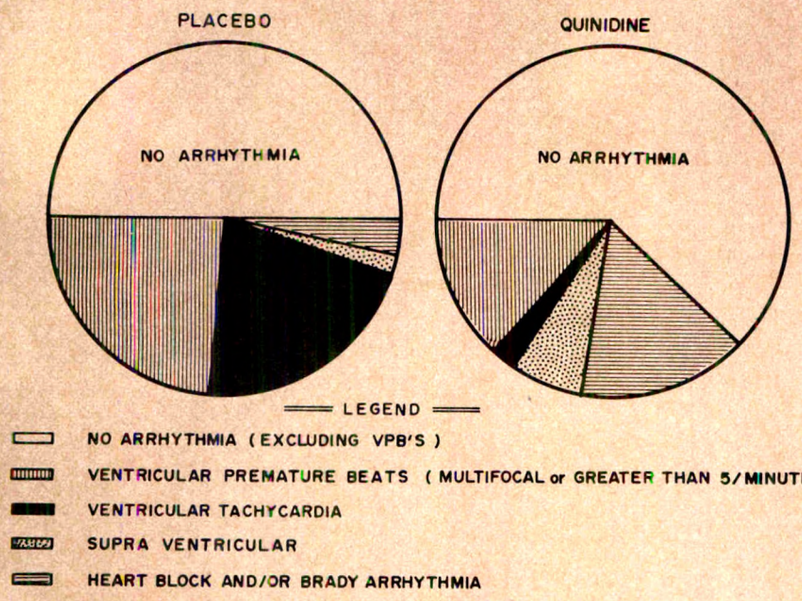

FIGURE 1. Relative frequency of arrhythmias after myocardial infarction in 58 patients receiving placebo and 45 receiving quinidine. Data exclude ventricular premature beats that were not multifocal or occurred less frequently than 5/min.

can reduce the frequency of ventricular dysrhythmia and sudden death. The desirability of an oral prophylactic antiarrhythmic agent, the encouraging results of animal studies, the conflicting evidence of earlier clinical trials and the availability of techniques for continuously monitoring patients who have recently had a myocardial infarction prompted this reappraisal of the value of orally administered prophylactic quinidine in myocardial infarction.

Methods

Case material: All patients admitted to the coronary care unit of Victoria Hospital from January 1968 until March 1970 were considered for inclusion in the study if they had experienced the onset of symptoms within the preceding 24 hours and were free from shock, acute congestive failure and serious arrhythmia. The arrhythmias excluding patients from the study were supraventricular tachycardia, ventricular tachycardia and ventricular premature beats that were multifocal or occurred with a frequency greater than 5/min. Patients found to have bundle branch block, atrioventricular (A–V) dissociation or a history of sensitivity to quinidine were also excluded.

During this period 538 patients were admitted, and 246 were considered suitable for the study. They were assigned randomly[18] to treatment by quinidine or placebo, with use of a double blind protocol. This procedure was considered desirable to avoid influence on the nursing staff and physicians in interpreting the electrocardiograms monitored in the coronary care unit and in later reviewing the continuous electrocardiogram recorded on magnetic tape in each patient for 72 hours or until his removal from the study.

Patients were continued in the study and included in the final evaluation only if the diagnosis of acute myocardial infarction was confirmed by the following criteria: (1) typical cardiac ischemic pain with Q waves in the electrocardiogram or T wave inversion with loss of the accompanying r wave, and S–T segment elevation; (2) typical cardiac ischemic pain followed by significant serial elevation of serum enzyme levels (glutamic oxaloacetic transaminase, lactic dehydrogenase, creatine phosphokinase) and S–T or T wave changes in the electrocardiogram; (3) in the absence of typical chest pain, sequential electrocardiographic changes as defined in the first criterion.

Protocol: All patients entering the study received oral doses of quinidine sulfate, 0.4 g, or identical placebo tablets of sodium lactate every 8 hours. Treatment continued for a total of 72 hours or until the patient was withdrawn from the study because of failure to satisfy the cited diagnostic criteria for acute myocardial infarction or because of treatment failure. The drug was routinely administered at 6:00 AM, 2:00 PM and 10:00 PM. Patients admitted within 3 hours after these times were given a full dose of the drug; those admitted between the 3rd and 6th hours received a half dose, and those admitted in the 2 hours preceding the next scheduled dose were given no drug.

During the latter part of the study, 128 blood samples for serum quinidine determinations were drawn from 73 patients between 9:00 and 10:00 AM on the 1st and 3rd days of the study. Analysis was made by the fluorometric method of Brodie and Undenfriend[19] and Edgar and Sokolow[20]; the results were unavailable until completion of the study.

In the coronary care unit a standard 12 lead electrocardiogram was obtained on admission and daily. Each patient's electrocardiogram was continuously displayed on an oscilloscope, and paper records of 10 seconds' duration were obtained at 15 minute intervals. Treatment decisions were based on these observations by the nursing and medical staff of the coronary care unit.

In addition, a continuous electrocardiographic record throughout the entire 72 hours of the study was recorded on magnetic tape at a hospital station that was not geographically part of the coronary unit. These records were made on Phillips FM 7 channel tape recorders, model 400, which were controlled so that a continuous uninterrupted record could be made. These tapes were reviewed independently by two observers, one a trained nurse technician, the other one of the authors. These observers documented arrhythmias appearing on the tapes and specifically noted the number of premature ventricular beats occurring over the 72 hour study period.

Treatment failure: Patients were withdrawn from the study and the appropriate therapy was instituted if failure

of the prophylactic antiarrhythmic treatment was manifested by: (1) the development of ventricular premature beats that were multifocal or had a frequency greater than 5/min, or the occurrence of an R on T phenomenon; (2) ventricular tachycardia or ventricular fibrillation; (3) A–V block greater than first degree; or (4) bundle branch block. Patients were also withdrawn from the study if they manifested shock, acute left ventricular failure or apparent intolerance to the medication.

Of the 246 patients, 103 satisfied the criteria for acute myocardial infarction and were included in the final evaluation. On completion of the study, when the drug code was broken, 58 patients had been receiving placebo and 45 had been receiving quinidine.

The success of the quinidine prophylaxis was evaluated by the following criteria: (1) treatment failure and the arrhythmia responsible for it; (2) quantitation of ventricular premature beats; (3) mortality during the 72 hours of controlled observations; and (4) serum levels of quinidine.

Results

Treatment Failure

The specific arrhythmias resulting in treatment failure are shown in Figure 1. The 38 percent prevalence rate of arrhythmias of all types in the quinidine-treated patients compared with the 50 percent rate in the group receiving placebo suggests a protective effect of quinidine; however, the difference is not statistically significant.

Ventricular tachycardia occurred in 12 of 58 patients treated with placebo and in only 1 of 45 treated with quinidine (chi-squared df2 $P < 0.01$). Ventricular premature beats that were multifocal or had a frequency greater than 5/min resulted in treatment failure in 14 of 58 patients treated with placebo and in only 6 of 45 patients receiving quinidine.

Thus, clinically disturbing ventricular tachyarrhythmias were observed during the first 72 hours in 26 of 58 patients (45 percent) who received the sodium lactate placebo and in only 7 of the 45 patients (16 percent) who received quinidine ($P < 0.05$). Supraventricular arrhythmias were too infrequent to permit a useful comparison. Bradyarrhythmias including heart block were considered serious enough to warrant discontinuance of the trial in 6 of the 45 quinidine-treated patients and in 2 of the 58 patients receiving placebo.

The time at which the occurrence of serious arrhythmia required discontinuance of the trial is shown in Figure 2. The data show an expected predominance of serious arrhythmia early in the first day of the study and reveal no significant differences between the two groups in the time of treatment failure on the first, second or third day.

Quantitation of Ventricular Premature Beats

Twenty-eight patients treated with quinidine and 27 receiving placebo completed the study without serious arrhythmia. The number of ventricular premature beats in each 24 hour period as well as the 72 hour totals were determined (Fig. 3 and 4). Both groups of patients had fewer ventricular premature beats per 24 hour period on successive days.

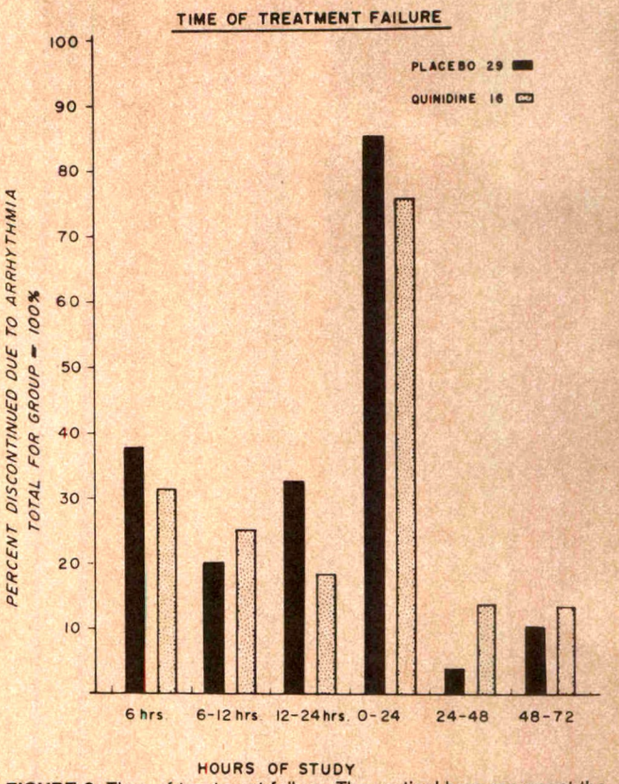

FIGURE 2. Time of treatment failure. The vertical bars represent the percent of patients in each group, placebo- and quinidine-treated, who were withdrawn from the study because of serious arrhythmia during the time intervals shown. Arrhythmias were more frequent in the first 24 hours. There was no systematic difference between the two groups in time of treatment failure.

The greater number of ventricular premature beats in the quinidine-treated patients was largely accounted for by two patients. In one, the number of ventricular premature beats exceeded the sum of ventricular beats for all placebo-treated patients, and in the other almost equaled this sum. Because of the wide scatter of the observations, the difference of the means has no significance. By day 3, 78 percent of the patients receiving placebo and 82.5 percent of those receiving quinidine had fewer than 10 ventricular premature beats per 24 hour period (Fig. 3).

Mortality

The total hospital mortality rate was similar in the two groups: 10.4 percent for patients receiving placebo and 8.9 percent for those receiving quinidine. During the 72 hour study period two patients receiving placebo died of cardiogenic shock. One patient treated with quinidine died within 24 hours. Because this patient first manifested frequent ventricular premature beats, administration of quinidine was discontinued and replaced by treatment with lidocaine. Ventricular fibrillation later occurred and, after successful defibrillation, evidence of bundle branch block noted on the electrocardiogram was followed by a dying heart pattern.

Upon completion of the study and after transfer from the unit, four patients receiving placebo died, two of irreversible cardiac failure and two of sudden cardiac arrest on the 7th and 8th days after infarction. There were three sudden fatal cardiac arrests in the quinidine-treated group, on days 4, 7 and 14 after infarction. Only the patient who died on day 4 had been treated with quinidine for the full 72 hours; the other two had been withdrawn from treatment.

Serum Quinidine Levels

On completion of the study when the results of the serum quinidine concentrations became known, 55 samples containing quinidine had been drawn from 34 patients. The remainder of the 128 serum samples containing no quinidine had been drawn from patients receiving placebo. The 55 serum quinidine samples included some from patients later excluded from the study because infarction was not proved. Individual values are shown in Figure 5.

In nine patients, the initial serum quinidine concentration was below 3 mg/liter. Two of these nine were transferred from the coronary care unit when it was evident they did not have an infarction. Six of the remaining seven patients had a serum level higher than 3 mg/liter when the second sample was taken. Thus only 1 of 32 patients (3.1 percent) did not have a serum quinidine level of 3 mg/liter or higher. Eighty-two percent of samples yielded concentrations in excess of 3 mg/liter; only two samples were above 10 mg/liter.

Side effects: Of the 45 quinidine-treated patients, only 1 was withdrawn from treatment because of nausea and vomiting. Of an additional 77 patients who received quinidine but did not have a proved infarction, 1 was withdrawn from treatment because of nausea and vomiting. A significant prolongation of the Q–T interval was observed in two patients although significant QRS widening was not recorded. No urticarial or other toxic signs were noted.

Discussion

Our study of the efficacy of orally administered quinidine in acute myocardial infarction did not include that significant proportion of patients who die from this condition outside the hospital. Moreover, it did not include those admitted to a coronary unit with "pump" failure, shock or pulmonary edema, or those who obviously required immediate antiarrhythmic treatment with lidocaine, propranolol or other agents. Its focus was on that group of good-risk patients in initially stable condition who would usually be monitored in a coronary care unit for 3 or 4 days and then be transferred to other accommodations if the clinical course was satisfactory. The duration of prophylactic drug administration, 72 hours, was chosen because of the generally acknowledged high frequency of serious arrhythmias within this period. Although one objective was to determine whether sudden death could be prevented, an important second objective was to quantitate the arrhythmias occurring in the treated and control groups by reviewing continuous magnetic tape recordings of the electrocardiogram over the entire 72 hours of observation.

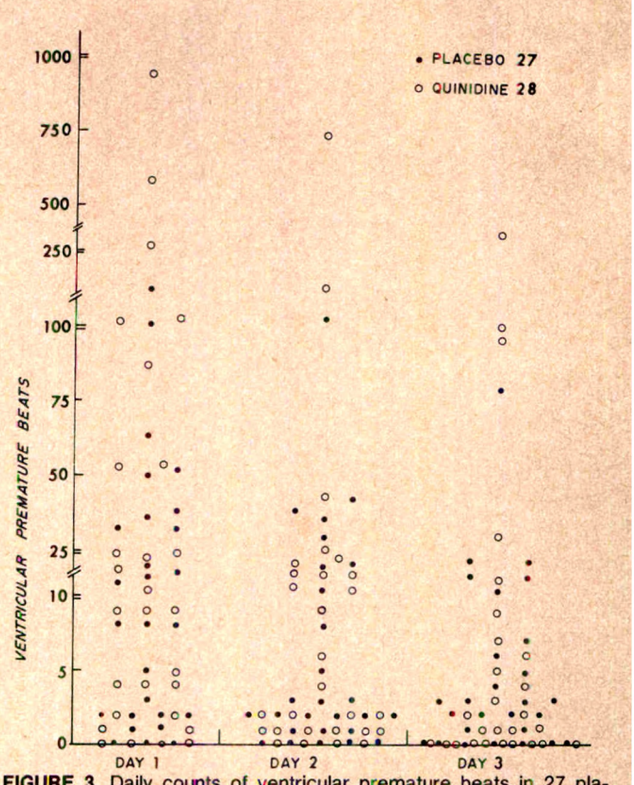

FIGURE 3. Daily counts of ventricular premature beats in 27 placebo-treated and 28 quinidine-treated patients who completed the 72 hour monitoring period without a serious arrhythmia. For each 24 hour period, a closed or open circle marks on the ordinate scale the number of premature beats counted from the magnetic tape record of a single patient.

Effect on survival: The almost identical in-hospital mortality in the two groups indicates that quinidine prophylaxis for 72 hours had no effect on ultimate survival. This is an expected finding since only 3 of the 103 patients died in the first 72 hours. Five patients died suddenly, presumably of ventricular arrhythmia, 4 to 14 days after infarction and after the study period. The occurrence of these late sudden deaths raises the question whether monitoring should be continued for more than the usual 3 to 5 days and suggests that trials of a prophylactic antiarrhythmic regimen should be maintained for 10 to 14 days. Indeed, since our study was conceived, Grace[21] has documented the importance of postcoronary care unit monitoring. Moreover, the Inter-Society Commission for Heart Disease Resources has recommended the inclusion of an intermediate coronary care unit adjacent to or in continuity with the coronary care unit.[22] Such a unit would allow for the management of patients with acute myocardial infarction during the phase of illness when risk of complications, particularly ventricular arrhythmia, has diminished appreciably but not completely.

Effect on prevalence of ventricular tachyarrhythmias: This study has shown that quinidine sulfate administered orally in a dose of 0.4 g every 8

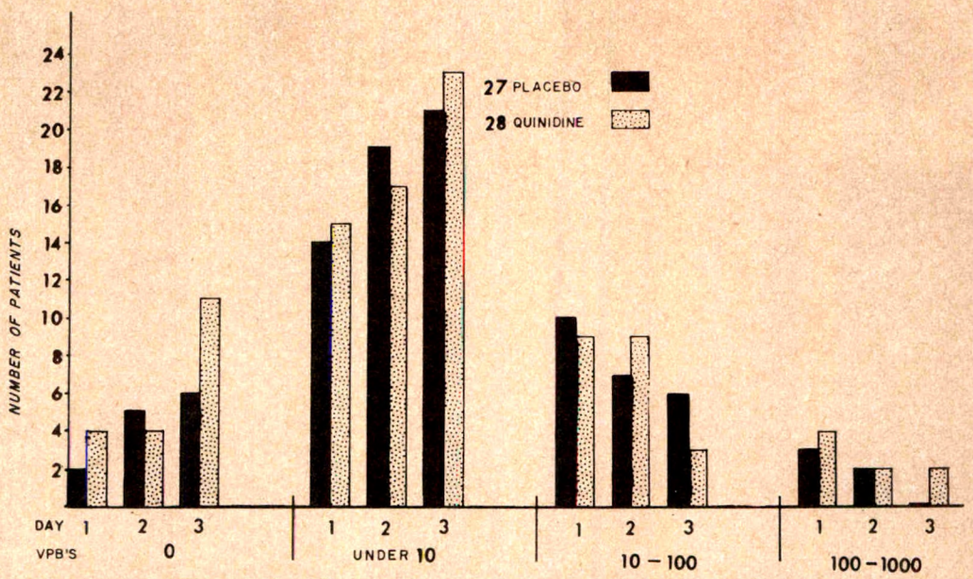

FIGURE 4. Patients who completed 72 hours of monitoring without a serious arrhythmia have been divided for each day of the study into four groups based on the number of isolated ventricular premature beats (VPB's) counted on the 24 hour magnetic tape record. The number of patients with fewer than 10 or no ventricular premature beats increased by the third day; the number with 10 to 100 and 100 to 1,000 decreased by the third day. There is no systematic difference between the quinidine- and placebo-treated groups.

hours will significantly reduce the prevalence of ventricular tachycardia after acute myocardial infarction. It will also significantly reduce the occurrence of ventricular premature beats that are multifocal or have a frequency greater than 5/min. The overall reduction in tachyarrhythmias (from 45 percent in the group receiving placebo to 16 percent in the group receiving quinidine) might be expected to decrease the risk of sudden death if the period of prophylactic therapy were extended beyond 72 hours. The earlier experimental work of de Boer[23] and Wiggers and Wegria[24] and the importance of the R on T phenomenon, first described by Smirk[25] and more recently confirmed in many coronary care unit monitoring programs, strengthen the thesis that both prevention and active treatment of ectopic electrical activity should reduce the risk of sudden death in the early postinfarction period.

Our study affords no encouragement that infrequent isolated ventricular premature beats can be in-

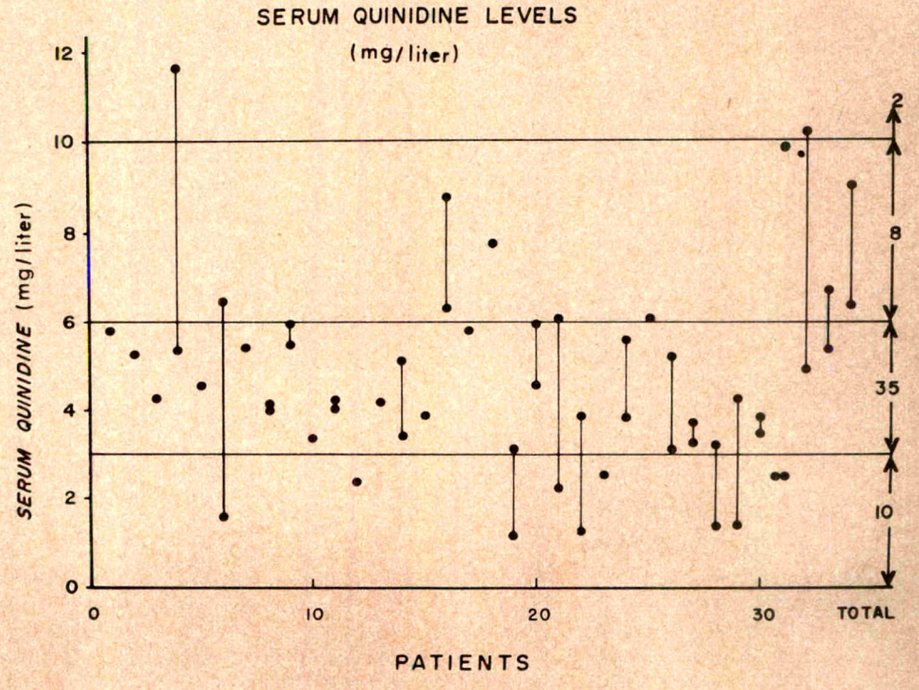

FIGURE 5. Serum quinidine concentrations in 55 samples from patients receiving 0.4 g of quinidine by mouth every 8 hours. **Closed circles** directly superimposed or connected by vertical lines designate the concentration on the first **(bottom)** and third **(top)** days in the same patient.

fluenced by an oral quinidine regimen. There was no significant difference between the groups receiving quinidine and placebo in respect to mean number of isolated ventricular premature beats per 24 hours even when the extremely high values of two quinidine-treated patients were excluded. There was a clear reduction in the total number of ventricular premature beats from the first to the third days but no systematic difference between the two groups. A significant difference was demonstrable when the groups were compared with respect to the number of treatment failures occasioned by the occurrence of ventricular premature beats that were multifocal or had a frequency greater than 5/min.

Serum quinidine levels and cumulation of drug: Some cumulation of quinidine is known to occur during the first 3 days of oral administration,[26] and in many of our patients, serum quinidine levels were higher on the third than on the first day. If the higher levels achieved later in the treatment period were of critical therapeutic significance, it would be expected that the protective effect of quinidine would be more evident at these later times. The data displayed in Figure 2 indicate that there was no systematic difference between the placebo- and quinidine-treated groups in respect to time of treatment failure manifested by a serious arrhythmia. Cumulation of the drug over the 72 hour period, therefore, did not appear to influence the results. On oral regimens of quinidine maximal serum concentration is achieved in 1 to 3 hours after ingestion and is relatively well maintained for 6 to 8 hours, with some cumulation in the first 12 hours but not thereafter.

The reduction in frequency of tachyarrhythmias due to quinidine was at the expense of a modest increase in bradyarrhythmias and A–V dissociation. Two patients were categorized as treatment failures for what could be considered side effects of quinidine. The first had atrial tachycardia with varying block with bradycardia and serum quinidine concentrations of 6.0 and 7.6 mg/liter. The second had serum quinidine levels of 2.1 rising to 6.0 mg/liter on the third day before treatment was discontinued because of nodal bradycardia (rate 40/min).

Acknowledgment

We are indebted to the late Mr. G. Steward, Technical Director, Cardiovascular Unit, Victoria Hospital, who designed and supervised the mechanism for the remote recording of the 72 hour tapes on these patients. We are also indebted to Ms. G. Aggersbury, RN, and Ms. A. Thompson, RN, who reviewed the tapes and assisted in compiling the data.

Comprehensive Treatment Plan for the Prevention of Primary Ventricular Fibrillation in Acute Myocardial Infarction

MILFORD G. WYMAN, MD, FACC
LUCILLE HAMMERSMITH, RN

San Pedro, California

This report of 1,165 cases of acute myocardial infarction outlines a method for preventing primary ventricular fibrillation in patients with this lesion. The plan of prevention begins in the emergency room, with every patient suspected of having myocardial infarction receiving an intravenous bolus injection of lidocaine, 75 mg, followed by a 2 mg/min infusion controlled by an infusion pump. If administration of lidocaine is ineffective (19 percent of cases), procainamide is given intravenously in a dose of 100 mg every 5 minutes, repeated as necessary to a maximum of 1 g and followed by an infusion of 2 to 6 mg/min. Ventricular tachycardia is rapidly converted to sinus rhythm by either drug or electrical therapy. Monitoring by telemetry is continued after the patient's discharge from the coronary care unit. A new episode of sustained chest pain requires the reinstitution of prophylactic lidocaine therapy.

Important precautions to control the toxic effects of these intravenous medications can be achieved in the community hospital where the nursing staff makes the decision to increase the dose of lidocaine or to substitute procainamide. There has been no recognized mortality from the use of these drugs as outlined. With this total system of care, the prevalence rate of primary ventricular fibrillation has been decreased from 6.5 percent (9 of 139 cases) to 0.3 percent (3 of 1,026 cases) and no deaths have occurred.

Prevention and treatment of primary ventricular fibrillation during the course of an acute myocardial infarction are the most important functions of the coronary care unit. Despite the reduced incidence of this type of cardiac arrest since the advent of such units, continued reports emphasize both the occurrence and associated mortality of primary ventricular fibrillation.[1–8]

These studies have raised the following questions: (1) Is primary ventricular fibrillation always preceded by "premonitory" arrhythmias? (2) Once premonitory arrhythmias occur, is there sufficient time for the institution of drug therapy to prevent primary ventricular fibrillation? (3) Are the currently used drugs effective in suppressing these premonitory arrhythmias or preventing primary ventricular fibrillation?

The purpose of this report is to answer these questions and describe a method for preventing primary ventricular fibrillation. The technique has been developed over the past 7 years in a community hospital with neither a full time unit director nor house staff. This plan of treatment has reduced the prevalence rate of primary ventricular fibrillation from 6.5 percent (9 of 139 cases) to 0.3 percent (3 of 1,026 cases).

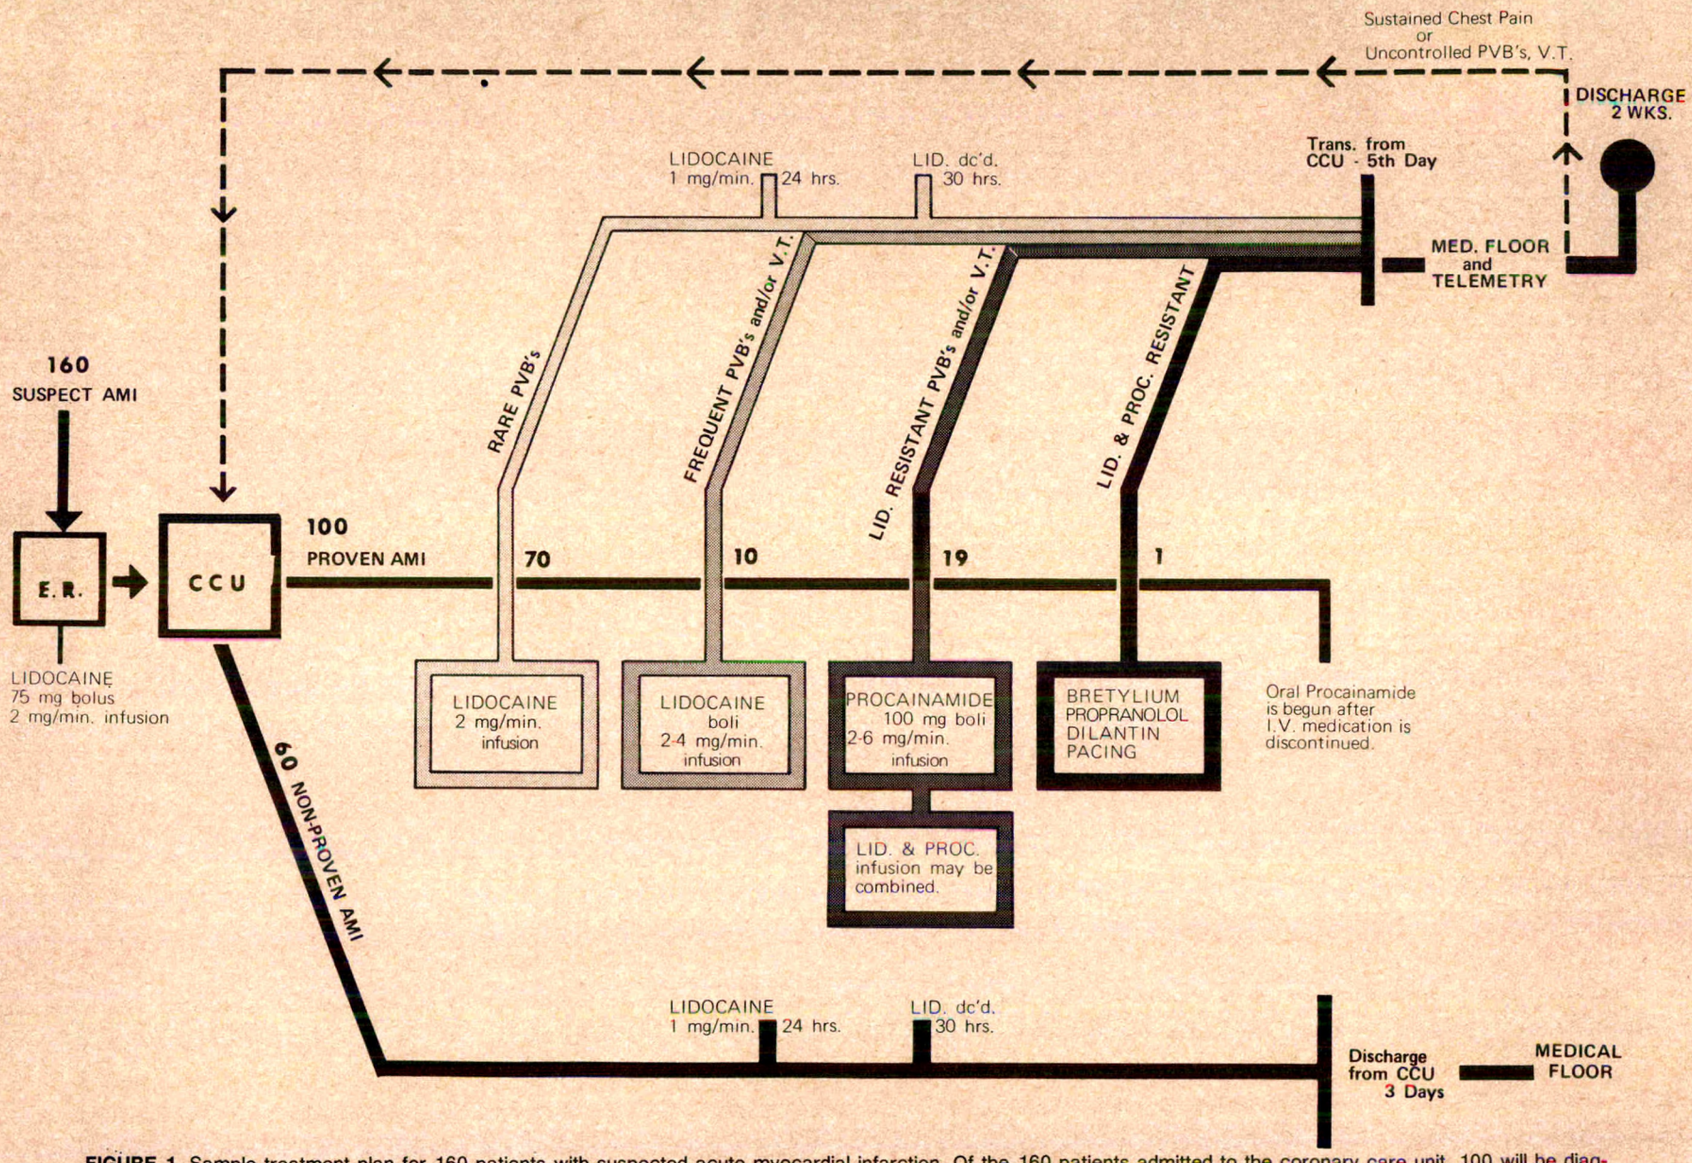

FIGURE 1. Sample treatment plan for 160 patients with suspected acute myocardial infarction. Of the 160 patients admitted to the coronary care unit, 100 will be diagnosed as having had an acute myocardial infarction. The plan represents treatment given to the last 611 patients with proved infarction. AMI = acute myocardial infarction; boli = bolus injection; CCU = coronary care unit; E.R. = emergency room; I.V. = intravenous; LID. = lidocaine; MED. = medical; PROC = procainamide; PVB's = premature ventricular beats; VT = ventricular tachycardia.

Methods

The data were collected during a 7 year period in a 165 bed community hospital that has neither house staff nor a full time unit director. All patients (1,165) diagnosed as having an acute myocardial infarction since the inception of the unit in 1966 were included in the study. The criteria for the diagnosis of acute myocardial infarction have been previously described[9] and were the same as those used for the diagnosis of myocardial infarction in the California Regional Medical Program Study. Analysis of the electrocardiograms revealed new or significant change in preexisting Q waves in 78 percent of cases and evolutionary S–T and T wave changes without Q waves in 22 percent. All patients had significant rises in serum enzyme levels with at least a 100 percent increase in serum glutamic oxaloacetic transaminase and creatine phosphokinase. In this series 23 percent of all deaths occurred in the group without Q waves.

Primary ventricular fibrillation was defined as fibrillation occurring in the absence of pulmonary edema or shock. All cases of secondary fibrillation occurred as an agonal event or when the patient had profound shock or pulmonary edema. Only cases of primary ventricular fibrillation occurring in the coronary care unit were included. The average duration of stay in the unit was 4.5 days.

Arrhythmias were documented in the coronary care unit with standard monitoring equipment utilizing an alarm-triggered electrocardiogram, a memory loop and, in selected cases, a 10 hour continuous tape. Both lidocaine and procainamide were administered to patients by the nurse, as directed by a set of standing orders. Ventricular tachycardia was immediately terminated electrically (direct-current capacitor discharge) by the nurse if clinical deterioration occurred. Serum potassium determinations were performed in all patients on admission to the unit, and potassium replacement was begun immediately if hypokalemia existed.

Treatment Plan

In Group I (the first 139 patients with confirmed acute myocardial infarction), prophylactic treatment was limited to orally administered procainamide or quinidine when multiple premature ventricular beats were observed. The doses were 250 or 500 mg of procainamide or 200 or 400 mg of quinidine every 4 to 6 hours, as determined by the attending physician. Ventricular tachycardia was treated with an intravenous infusion of procainamide at a rate of 50 to 100 mg/min until the arrhythmia was abolished or 1 gram of procainamide had been given. Electrical conversion was used if clinical deterioration was evident or if the use of procainamide had been unsuccessful.

In Group II, (the last 1,026 patients with confirmed acute myocardial infarction), prophylactic intravenous administration of lidocaine was begun, and, if unsuccessful, procainamide was given intravenously. In the first subgroup (IIA, 145 patients) the criteria for initiating a lidocaine drip infusion were as follows if premature ventricular beats: (1) occurred on the T wave, (2) occurred in bursts (two in succession), (3) were multifocal, or (4) exceeded a rate of 5/min. In the second subgroup (IIB, 270 patients) prophylactic administration of lidocaine was begun when the first premature ventricular beat was observed. The third subgroup (IIC, 611 patients) reflects the current procedure of administering lidocaine to every patient with suspected myocardial infarction.

The treatment plan for every patient with suspected myocardial infarction begins in the emergency room. The doses of lidocaine, and procainamide if needed, are as follows: Lidocaine, 50 mg, is given intravenously as a bolus injection, followed by 25 mg over the next minute. A 2 mg/min drip infusion is then begun and continued over the next 24 hours. It is then slowly diminished and discontinued over the next 6 hours if no premature ventricular beats are observed. The patient is then given procainamide, 250 mg orally, every 4 hours until discharge from the hospital. If the premature ventricular beats are not controlled by the 2 mg/min infusion of lidocaine, a second and, if necessary, a third bolus injection of lidocaine is given, and the infusion rate is increased to a maximum of 4 mg/min. If lidocaine is ineffective at this dose, intravenous administration of procainamide is started. An infusion of 100 mg is given every 5 minutes and repeated as necessary (not to exceed 1 gram) to suppress ventricular extrasystoles. This is followed by infusion at a rate of 2 mg/min, which may be increased to 6 mg/min. The two drugs given in combination have appeared at times to have a more suppressant effect than either alone. If ventricular tachycardia ensues (rates over 100/min) and is sustained despite drug treatment, electrical conversion is immediately carried out.

After the patient is discharged from the coronary care unit to the ward, an intravenous pathway is maintained for 48 hours. Monitoring by telemetry is continued during the convalescent period. A patient experiencing a new episode of sustained chest pain during the convalescent period again receives prophylactic intravenous infusions of lidocaine. A flow chart of the entire treatment plan is shown in Figure 1.

The dose of lidocaine or procainamide is halved if shock, serious congestive failure or renal failure is present, since lidocaine is primarily detoxified by the liver and procainamide by the kidney.[10,11] Blood pressure and QRS duration are carefully monitored when procainamide is given. Administration of this drug is withheld in the presence of second or third degree atrioventricular (A–V) block if a pacing catheter has not been inserted. If muscular twitching or change in sensorium is noted during the administration of lidocaine, the dose is decreased. Premature or escape ventricular beats resulting from sinus bradycardia or bradycardia due to heart block require increasing the ventricular rate by administration of atropine or cardiac pacing. If the ectopic beats continue after the ventricular rate is increased, suppressant therapy will be given as previously outlined.

The following rules have been developed to prevent lidocaine toxicity:

1. All patients receive lidocaine by infusion pump.
2. Lidocaine is not given at a rate higher than 4 mg/min.
3. The dose of lidocaine is halved in the presence of severe congestive failure or shock.
4. In uncontrolled atrial arrhythmias, the ventricular rate is slowed before treatment with lidocaine is begun.[12,13]
5. If ectopic ventricular beats appear to be enhanced by lidocaine (a rare occurrence), intravenous infusion of procainamide is substituted.

Results

Prevalence and clinical factors: The mortality rate for the total series of 1,165 patients with acute myocardial infarction was 10.2 percent. The mean age of all patients in the series was 63 years. Shock occurred in 10 percent, and moderate or severe congestive failure in 25 percent. Time from onset of pain until hospital admission was calculated in each case.

TABLE I

Prevalence of Primary Ventricular Fibrillation Before and After Use of Prophylactic Intravenous Administration of Lidocaine or Procainamide

	Patients with Proved AMI (no.)	Criteria for Prophylaxis	Prophylaxis Plan	Primary VF (no. of cases)	Primary VF (%)
Group I	139	Multiple PVBs	Procainamide or quinidine (orally)	9	6.5
Group II	1,026	...	Lidocaine (intravenous bolus	3	0.3
A	145	"Standard" criteria	injection, then infusion to 4	0	...
B	270	1st PVB	mg/min); if unsuccessful,	1	...
C	611	On admission with suspected AMI	procainamide (intravenous bolus injection, then infusion to 6 mg/min)	2	...

AMI = acute myocardial infarction; PVB = premature ventricular beat; VF = ventricular fibrillation.

Fifty-eight percent of patients were admitted within 4 hours of onset and 29 percent within 1 hour of onset. Pump failure was the cause of death in all cases except for one case of primary ventricular fibrillation. Primary ventricular fibrillation occurred in 12 patients in the entire series; 1 of the 12 died despite immediate defibrillation. The other 11 were discharged from the hospital and are alive 6 to 84 months after the event. Table I shows the prevalence of primary ventricular fibrillation before and after prophylactic use of lidocaine and, if necessary, procainamide. Before this procedure was adopted, the prevalence rate of primary ventricular fibrillation was 6.5 percent (9 of 139). After its adoption, primary ventricular fibrillation occurred 3 times in 1,026 cases (0.3 percent).

Premonitory cardiac arrhythmias: Table II shows the characteristics of the 12 patients with ven-

TABLE II

Characteristics of Patients with Primary Ventricular Fibrillation

Case no.	Age (yr) & Sex	Time (hours) From Pain to Admission	Time (hours) From Admission to Fibrillation	Time (hours) From Pain to Fibrillation	Site of Infarct	Premonitory Rhythm	Prophylactic Medication	Outcome
1	44M	1	1	2	Inf	Sinus with PVBs	None	A
2	45M	1	2	3	Inf	Sinus tachycardia with PVBs	None	A
3	53M	1	2 1/2	3 1/2	Inf	Sinus with PVBs	Lidocaine (3 mg/min)	A
4	54F	1	1	2	Inf	Sinus with PVBs	Quinidine	A
5	56M	1	15	16	Inf	Atrial flutter with rare PVB	Digitalis; none	D
6	58M	1	3	4	Ant	Sinus with no PVBs	None	A
7	60M	3	137	140	Inf	Atrial flutter with rare PVB	Procainamide (orally); lidocaine (intravenously, 2 mg/min)	A
8	63M	2	10	12	Inf	Sinus with rare PVB	None	A
9	63M	12	20	32	Ant	Junctional with rare PVB	Quinidine	A
10	69M	12	1/3	12	Ant	Sinus with rare PVB (R on T)	None	A
11	71F	3	2	5	Ant	Sinus with rare PVB (R on T)	Quinidine	A
12	77F	6	3	9	Inf	Junctional with PVBs	None	A

A = alive; Ant = anterior; D = died; Inf = inferior; PVB = premature ventricular beat.

tricular fibrillation. More than half (7 of 12) were 60 years of age or less; the average age was 59. In 8 of the 12, ventricular fibrillation developed within 3 hours of the patient's admission to the coronary care unit; in 6 of the 12, it occurred within 5 hours of the onset of pain. In seven, only a rare or no premature ventricular beat was noted before the onset of the fibrillation. No episode of primary ventricular fibrillation was immediately preceded by ventricular tachycardia or preceded at any time by sinus bradycardia, junctional bradycardia or A–V block. Two episodes occurred after inadequate control of atrial flutter. The single death from primary ventricular fibrillation occurred before the use of lidocaine. This patient had atrial flutter with a ventricular rate of 150/min. Digoxin was given intravenously, but shortly thereafter, with only a rare ectopic ventricular beat, ventricular fibrillation occurred. Defibrillation was unsuccessful.

In one patient (Group IIB) with primary ventricular fibrillation there were no preceding ectopic ventricular beats, as documented with use of a 20 minute memory loop. This occurrence of primary ventricular fibrillation without any warning prompted the initiation of prophylactic lidocaine therapy to all patients with suspected myocardial infarction (Group IIC). One patient in this latter group had ventricular fibrillation on the fifth hospital day. His course was complicated by hypotension, heart failure, multiple pulmonary emboli and atrial fibrillation and flutter. Despite intravenous administration of digitalis, the ventricular rate was not adequately slowed, and during one of many episodes of atrial flutter, ventricular fibrillation ensued, which was converted to sinus rhythm by direct-current defibrillation. At the time of the ventricular fibrillation, the patient was receiving a 2 mg/min infusion of lidocaine. The second patient in Group IIC who demonstrated ventricular fibrillation was given a 3 mg/min infusion of lidocaine after a brief run of bigeminy. No ectopic ventricular beats were noted for 15 minutes before the occurrence of ventricular fibrillation.

Treatment outside the coronary care unit: The prevalence data on primary ventricular fibrillation in this report have included only those documented cases occurring in the coronary care unit. The treatment program during the 7 years was expanded to include the emergency room area and the general medical floor. In those patients who received lidocaine therapy in the emergency room (last 611 cases), no cases of primary ventricular fibrillation occurred either in the emergency room, on the elevator or in the halls as the patient was transported to the unit. Three cases of primary ventricular fibrillation occurred in the emergency room before intravenous tubing could be inserted and lidocaine administered.

Monitoring after discharge from the unit was used in the last 810 cases. Sudden death has rarely occurred since the addition of this step to the program. Five patients died suddenly on the medical floor, but the arrhythmia at the precise moment of clinical death was not recorded since the telemetric equipment has no memory loop. Two of these patients underwent autopsy; one had a large fresh pulmonary embolus in the left main pulmonary artery, and one a fresh occlusion of the left main coronary artery.

Other treatment for ventricular arrhythmias: It was necessary to supplement or replace lidocaine with procainamide in 19 percent of patients because of inadequate control of the ectopic ventricular rhythms. In less than 1 percent of patients requiring procainamide, the ventricular rhythm still could not be controlled. Diphenylhydantoin, bretylium tosylate, propranolol hydrochloride or overdrive pacing was then used. Rapid ventricular tachycardia was quickly and successfully converted to sinus rhythm by chemical or electrical therapy.

Accelerated idioventricular rhythm was generally controlled by administration of atropine. However, a gradual acceleration of the focus was commonly observed and, in these instances, lidocaine or procainamide proved effective. In two patients with an accelerated idioventricular rhythm, a 2:1 exit block was recognized when the ventricular rate exceeded 160/min. It should be pointed out that most ectopic ventricular rhythms occur in the first 24 hours of an acute myocardial infarction; in some instances, it is difficult to determine if time alone is as important as drug therapy in controlling the ventricular rhythms. In others, a prior history of ventricular premature beats is associated with difficulty in suppressing such a focus.

Lidocaine and Procainamide Toxicity

Lidocaine: This agent has been used in more than 1,550 patients since the inception of the coronary care unit. Infarction was documented in approximately 950 patients; more than 550 patients were found to have had no infarction. The latter patients experienced no significant side effects from the administration of lidocaine (75 mg bolus injection and a 2 mg/min drip infusion). Minor transient central nervous system complaints could be elicited after the initial bolus injection; spontaneous complaints were unusual. In the patients with documented myocardial infarction, effects on the central nervous system were dose-related. Three patients early in the series had convulsions caused by a "runaway" infusion. This complication has since been prevented by the use of infusion pumps in all patients. No adverse hemodynamic effects were found.

The effects of lidocaine on the sinus rate and P–R, QRS and Q–T durations were studied in 100 consecutive patients. These measurements were performed on the surface electrocardiogram every minute for the first 15 minutes after the initial 75 mg bolus injection, and then hourly for the ensuing 30 hours. No statistically significant effects were found. Twenty patients in this group had sinus rates of less than 60/min, and none manifested further slowing. Blood lidocaine levels were serially measured in 25 patients who had received the bolus injection plus the 2 mg/

min infusion. The results showed that no patient demonstrated drug buildup after administration of lidocaine for a 30 hour period.

Procainamide: Intravenously administered procainamide was used in 19 percent of patients because of the ineffectiveness of lidocaine. With this method of administration, serum procainamide levels did not exceed 10 mg/liter. Significant widening of the QRS duration was recognized in one case, and prolongation of the Q–T interval was frequently observed. Significant hypotension rarely occurred.

Discussion

As currently used throughout the world, lidocaine prophylaxis has reduced the mortality from acute myocardial infarction, but many patients still experience primary ventricular fibrillation and subsequently die. In many cases these deaths occur because the so-called premonitory ventricular rhythms are absent or unrecognized.[14] Bennett and Pentecost[8] clearly documented the absence of electrocardiographic warning in 27 patients with primary ventricular fibrillation: Five (19 percent) had no warning at all, 2 (7 percent) had warning for less than 5 minutes, and 20 (74 percent) had fewer than five premature ventricular beats per minute. In our study, 7 of 12 patients with primary ventricular fibrillation had no premonitory ventricular arrhythmias. In other studies[3–8] from 25 to 83 percent of such patients have had no warning arrhythmia.

Factors in prevalence of ventricular fibrillation: Prevalence data on primary ventricular fibrillation have been documented in only a few reports and have generally been limited to instances in the coronary care unit. The rates have ranged from 2.4 to 10 percent. Data on the prevalence of primary ventricular fibrillation in the emergency room and after discharge from the coronary care unit are sorely needed. Because most of the published reports are from units with both house staff and full time director and data from large numbers of community hospitals are lacking, it is not possible to estimate the true incidence of this potentially lethal complication. In a recent 3 year study[15]•conducted in 100 hospitals in California, the prevalence rate of primary ventricular fibrillation in the coronary care unit was 5 percent (793 of 15,031 cases), and 47 percent of these patients died. Of all the deaths that occurred in the entire study, 17 percent were due to a primary arrhythmia.

Two major factors other than treatment may account for differences in the prevalence rate of primary ventricular fibrillation from one hospital to another. The first is definition of the arrhythmia; the second, the rapidity with which patients are hospitalized.

Definition: The definition of primary ventricular fibrillation used in our study is more inclusive than that generally used.[16,17] In our hospital patients who have ventricular fibrillation accompanied by moderate congestive failure are classified as having primary fibrillation; only patients with pulmonary edema or shock are considered to have secondary ventricular fibrillation.

Time from onset of symptoms: The second factor that may influence the prevalence rate of primary ventricular fibrillation is the interval between onset of symptoms and hospitalization. In our study 58 percent of patients were hospitalized within 4 hours and 29 percent within 1 hour; this delay is generally less than that reported in other studies.[3–6,18,19]

Effect of treatment plan: Neither of the preceding factors accounts for the low prevalence rate reported here. Since our definition of primary ventricular fibrillation was more inclusive and our patients were hospitalized earlier during their acute myocardial infarction than in other reported series, the extremely low prevalence rate (0.3 percent) of primary ventricular fibrillation in our study must have resulted from the treatment plan.

This plan takes into account the multiple conditions that predispose the patient to primary ventricular fibrillation and deals with each in a specific manner. The high prevalence rate during the first hours and the lack of warning arrhythmias are countered by the use of lidocaine in every case of suspected myocardial infarction in the emergency room. There is evidence that lidocaine has a direct effect on the myocardium, decreasing its vulnerability to development of fibrillation.[20] The ineffectiveness of lidocaine in approximately 19 percent of patients is dealt with by the early use of intravenously administered procainamide. The danger of a rapid ventricular tachycardia degenerating into ventricular fibrillation is countered by rapid conversion to sinus rhythm by chemical or electrical means. The high rate of sudden death after a patient is transferred from the coronary care unit is prevented by telemetric monitoring until time of discharge, and reinstitution of prophylactic lidocaine therapy if a new episode of chest pain occurs or new bursts of ectopic ventricular beats are recognized.

Reports of controlled trials with routine antiarrhythmic prophylaxis have shown a reduction in ectopic ventricular rhythms but not in primary ventricular fibrillation; this finding is expected.[21–23] The control patients in all of the reported studies were given lidocaine as soon as premonitory ventricular arrhythmias were recognized and were therefore removed from the control population. In addition, the number of cases in each trial was small. A controlled trial of a plan involving multiple steps, such as that presented here, would be a difficult undertaking in a single hospital. A cooperative study involving several institutions may be able to test this treatment program. We believe that primary ventricular fibrillation is a preventable complication of acute myocardial infarction, requiring a plan that recognizes the precise time the patient is most susceptible and, in the absence of the physician, the initiation of prophylactic measures by nursing personnel.

Ostium Secundum Atrial Septal Defect Associated with Balloon Mitral Valve in Children

BENJAMIN E. VICTORICA, MD, FACC*
LARRY P. ELLIOTT, MD, FACC†
IRA H. GESSNER, MD, FACC*

Gainesville, Florida

Eight children with an ostium secundum atrial septal defect and balloon mitral valve are described. Leftward-superior QRS forces, abnormal T waves and suggestive apical auscultatory findings (midsystolic click or a late systolic murmur of mitral insufficiency) were frequently observed and led to the erroneous diagnosis of ostium primum atrial septal defect in six cases. Lack of any or all of these manifestations did not preclude the presence of a balloon mitral valve. The prognostic importance of this valvular lesion indicates the need to perform left ventriculography in all patients with an atrial septal defect.

Balloon mitral valve, also termed prolapsing or billowing mitral valve, is an anomaly characterized by aneurysmal protrusion of the posterior or anterior mitral valve leaflet, or both, into the left atrium, usually late during ventricular contraction. This lesion has been the subject of several reviews of data in large numbers of cases.[1–4] Although patients with an associated ostium secundum atrial septal defect have occasionally been included in the reported series,[5–9] the direct association of these lesions has only recently been reported.[10,11]

In this paper we emphasize the association of balloon mitral valve with ostium secundum atrial septal defect and report the clinical and laboratory findings in a series of eight children. Our observations indicate that a balloon mitral valve should be suspected in all children with an ostium secundum atrial septal defect, especially those who demonstrate unusual electrovectorcardiographic features or suggestive auscultatory findings. Identification of the lesion is important since these patients may be thought to have an ostium primum atrial septal defect (partial form of endocardial cushion defect) or may experience significant complications such as mitral valve insufficiency, potentially dangerous cardiac dysrhythmias or infective endocarditis.

Material and Methods

All eight patients were evaluated at the University of Florida Medical Center. Their ages ranged from 3 to 14 years; two were female. None had a history of rheumatic fever or showed signs of Marfan's syndrome. Complete studies including chest roentgenograms (four views with barium), phonocardiograms, 14 lead electrocardiograms and Grishman cube vectorcardiograms were obtained in all. Right and left cardiac catheterization with selective left ventriculography was performed in every patient.

Results

Clinical findings (Table I): Half of the patients were symptomatic, demonstrating decreased exercise tolerance. One patient had Noonan's syndrome (hypertelorism with Turner phenotype and normal chromosomes[12]), and three had evidence of mental retardation. All had clinical and X-ray findings compatible with an atrial septal defect. Three patients had an apical midsystolic click; one of these and another patient also had a murmur of mitral insufficiency.

TABLE I

Clinical and Electrocardiographic Findings

Case no.	Age (yr) & Sex	Apical Click	MI Murmur	Mean Frontal QRS Axis	ECG Diagnosis	T in V_6	Surgery	Associated Defects
1	3M	No	No	−30°	Normal	+	No	Mental retardation; seizures
2	3M	Yes	No	−60°	RVH	+	Yes	Functional speech defect; tricuspid valve insufficiency
3	7M	No	No	+150°	RVH	+	Yes	None
4	10M	No	Yes	+170°	RVH	−	Yes	None
5	11M	Yes	No	+130°	RVH	−	No	Noonan's syndrome
6	12F	No	No	+190°	RVH	+	Yes	Partial anomalous pulmonary venous return; pulmonic stenosis; mental retardation; congenital nystagmus
7	13M	Yes	Yes	Indeterminate	BVH	+	Yes	None
8	14F	No	No	+180°	WPW RBBB	+	Yes	Mental retardation

+ = positive; − = negative.

BVH = biventricular hypertrophy; MI = mitral valve insufficiency; RBBB = right bundle branch block; RVH = right ventricular hypertrophy; WPW = Wolff-Parkinson-White syndrome.

Electrocardiographic and vectorcardiographic findings (Table I): Two patients demonstrated premature supraventricular beats. Five patients had right axis deviation, two left axis deviation (Fig. 1) and one an indeterminate axis. Five patients manifested right ventricular hypertrophy, one had a normal tracing and the one patient with significant mitral insufficiency (Case 7) had biventricular hypertrophy. Patient 8 presented with Wolff-Parkinson-White syndrome and right bundle branch block. Two patients had negative T waves in lead V_6.

The majority of the frontal QRS loops were unusual for ostium secundum atrial septal defect (Fig. 2). Four patients (Cases 1, 2, 3 and 7) had a leftward QRS loop with counterclockwise or complex inscription. In four the loop had a clockwise inscription, but in three of these patients (Cases 4, 6 and 8) large rightward and superior terminal QRS forces were observed.

In six patients the diagnosis of an ostium primum atrial septal defect (endocardial cushion defect type) was made at the first clinical evaluation primarily on the basis of the electrocardiogram or vectorcardiogram, or both. In two patients (Cases 2 and 6) the erroneous diagnosis had been made previously after cardiac catheterization at another medical center.

Cardiac catheterization: The presence of a left to right shunt at the atrial level was demonstrated by

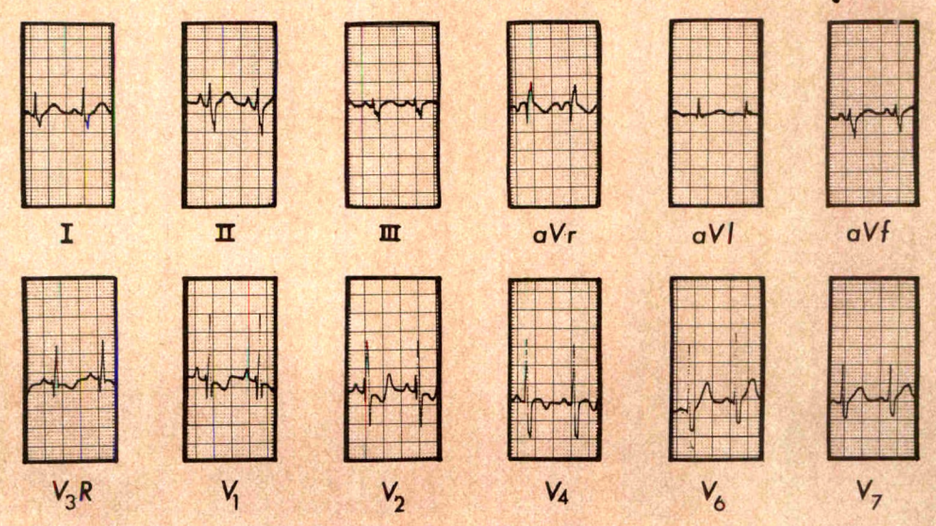

FIGURE 1. Case 2. Electrocardiogram revealing left axis deviation, right atrial enlargement and right ventricular hypertrophy.

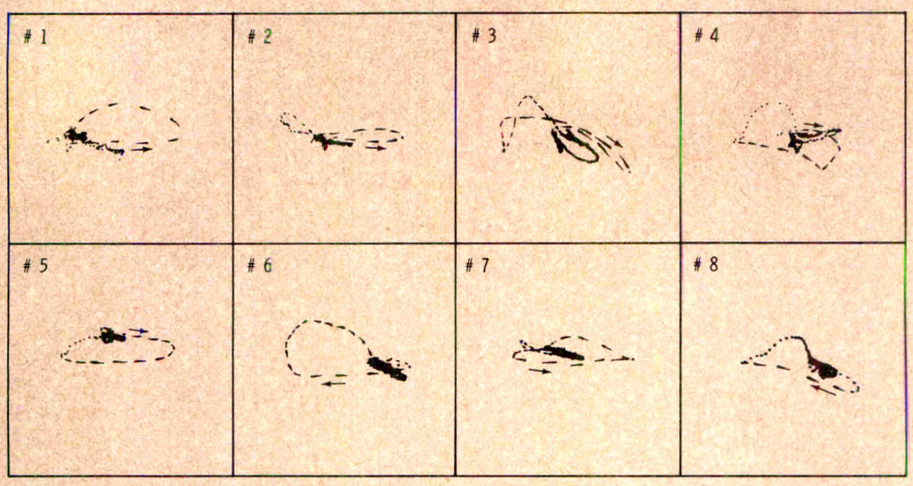

FIGURE 2. Frontal plane Grishman cube vectorcardiograms in eight cases. Cases 1, 2, 3 and 7 have leftward QRS loops with counterclockwise or complex inscription, similar to those observed in association with ostium primum atrial septal defects.

cardiac catheterization data in all patients. The pulmonary to systemic flow ratio (Qp/Qs) ranged from 1.3:1 to 5.5:1. Right ventricular peak systolic pressures were normal except in Patient 6, who had associated pulmonic stenosis.

Left ventriculography: Biplane seriographic anteroposterior and lateral view left ventriculography was performed in six patients and single plane left cineventriculography in the right anterior oblique projection in two. In each patient there was evidence of a ballooning or prolapsing mitral valve leaflet. The posterior or mural leaflet was involved in all eight cases; in four, the anterior (septal) leaflet was also deformed.

In the biplane studies the prolapsing mitral valve produced a distinct pattern in all six patients. In the anteroposterior projection, as contrast medium collected in the prolapsing component of the posterior leaflet, a sausage-like density appeared superimposed over the superior component of the medial and lateral walls of the outflow tract (Fig. 3A and 4B). In one patient with mitral valve incompetence this configuration was less apparent. In two patients who were rotated to a slightly right oblique position, the prolapsing leaflet projected as a discrete aneurysmal bulge along the medial aspect of the left ventricular outflow tract. This appearance is important since it can be confused with an aneurysm of the membranous portion of the ventricular septum. In the lateral view the prolapsing valve appeared as cauliflower-like projections directed posteriorly, seen best in systole (Fig. 3B).

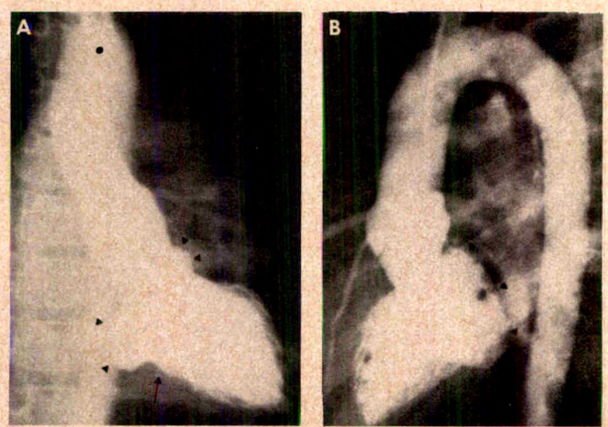

FIGURE 3. Case 6. Selective left ventriculograms (end-systolic films). **A,** anteroposterior view; **B,** lateral view. In **A,** the prolapsing mitral valve projects on both sides of the left ventricular outflow tract **(triangles).** There is a posteroinferior wall deformity **(arrow)** and an area of asynergism along the superior wall. In **B,** the triangles point toward the prolapsing valve.

The two patients undergoing right anterior oblique left cineventriculography also showed prolapse of the mitral valve into the left atrium. Of these, one had mitral valve incompetence.

Analysis of the motion of the left ventricle revealed that, although contractions were vigorous, three of eight patients had asynergistic contractions or relaxations; in each this was shown by an anterior convex bulging in the mid-aspect of the anterolateral wall in systole (Fig. 4A). In addition, one patient had a localized systolic indentation of the inferoposterior wall into the left ventricular cavity (Fig. 3A), and one patient demonstrated apical akinesia.

Of the two patients with mitral valve incompetence, one manifested the asynergistic abnormality of the anterolateral wall; in the other the ventricle contracted normally. We believe that analysis of ventricular motion in relation to asynergism is best accomplished by right anterior oblique cineventriculography rather than by seriography in the anteroposterior and lateral projections.

Surgical findings and treatment: Surgical closure of the ostium secundum atrial septal defect was accomplished in six patients. Two patients required a patch, Patient 4 because the defect was large and Patient 6 because of anomalous connection of the right pulmonary veins to the right atrium.

The mitral valve was examined in five patients: Two had no significant abnormality, but three had obvious changes. Patient 4 had a large prolapsing

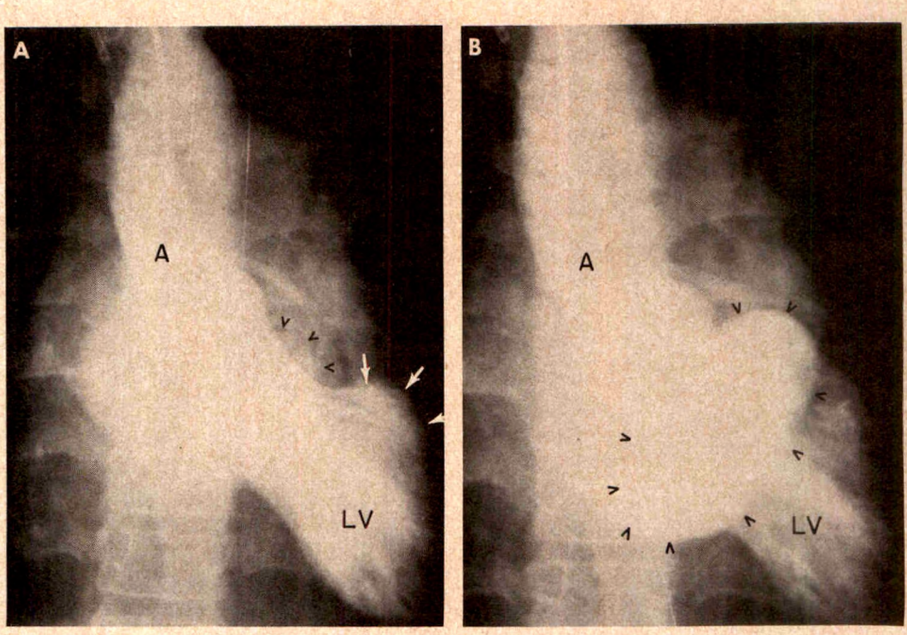

FIGURE 4. Case 7. Anteroposterior selective left ventriculograms. In **A**, mitral valve prolapse is seen on both sides of the left ventricular outflow tract, especially the lateral side (V). Because of mitral valve insufficiency, prolapse seen medially is less apparent because it is superimposed over contrast material in the left atrium. The **arrows** indicate the systolic bulge along the anterolateral wall of the left ventricle (LV). In **B**, the prolapsing mitral valve is more apparent in late systole and appears as a sausage-like mass (V).

posterior leaflet and Patient 6 a redundant anterior leaflet; in Patient 7 the mitral valve had a myxomatous appearance with thickened and prolapsed anterior and posterior leaflets. No cleft of the anterior leaflet was observed in any instance and nothing was done to the malformed valves. Patient 6 also underwent pulmonary valvotomy.

Postoperative cardiac rhythm disturbances were documented in every case. In two patients, right ventricular conduction delay developed. Two patients had temporary nodal rhythm, which in one was associated with complete right bundle branch block. Patients 4 and 8 had episodes of supraventricular tachycardia with variable second degree atrioventricular conduction.

Cardiac auscultation after operation revealed persistence of the murmur of mitral insufficiency in Patients 4 and 7. In the other patients, the apical click became apparent or more distinct. Postoperative cardiac catheterization studies were performed in two patients. In Case 2 the study disclosed no residual left to right shunt but revealed moderate tricuspid valve insufficiency. In Case 6 catheterization data demonstrated no residual shunt or pulmonic stenosis, but the left ventriculogram revealed persistent ballooning of the mitral valve with minimal insufficiency.

Discussion

Griffith[13] in 1892 first suggested that late apical systolic murmurs were due to mitral valve insufficiency, but it was not until 1963 that Barlow et al.[14] confirmed this observation by angiocardiography. The mitral origin of these characteristic murmurs and the frequently associated midsystolic click was also documented by phonocardiography.[15–17] The relation of these findings to prolapse of the valve was almost simultaneously reported by Barlow and Bosman[1] and by Criley et al.,[18] who found that the systolic click coincided with the maximal projection of the prolapsed valve into the left atrium. Reid[19] has theorized that the clicks are caused by "chordal snap" due to sudden tensing of the chordae tendineae. Four of our patients with an ostium secundum atrial septal defect had auscultatory findings suggesting an abnormal mitral valve. Three had an apical systolic click; one of these and another patient also had a late systolic murmur of mitral insufficiency. In Case 4 this murmur was detectable only when the patient was seated.[20] These observations indicate that careful apical auscultation with the patient in different positions should be performed in any case of atrial septal defect.

Differentiation from ostium primum defect: The electrocardiograms and vectorcardiograms were unusual for a secundum type of atrial defect. They were of particular significance in Patients 1 and 3, who had no detectable apical clicks or murmurs but who had a superior mean QRS axis or leftward and predominantly counterclockwise frontal QRS loops, or both. Patients 4 and 5 also had abnormal negative T waves in the left precordial leads, as previously described in patients with balloon mitral valve.[21]

These unexpected electrovectorcardiographic and apical auscultatory findings led to the erroneous clinical diagnosis of ostium primum atrial septal defect in six of our patients. The correct anatomy was confirmed by selective angiocardiography, which demonstrated that all patients had a normal left ventricular outflow tract (thus ruling out the presence of an endocardial cushion defect) as well as manifestations of ballooning mitral leaflets. The latter ranged from discrete protrusions on either side of the base of the left ventricle to gross deformity of both leaflets with dilatation of the mitral annulus.[22] In addition, areas of asynergistic contraction of the left ventricle were

commonly present. They manifested as an abnormal bulging in the midportion of the anterolateral wall or as an indentation of the inferoposterior wall into the left ventricular inflow tract.[23] Ehlers et al.[24] believe that the latter phenomenon is the result of a congenital anomaly in a localized area of the left ventricular myocardium, similar to the one recently described after myocardial infarction.[25] Grossman et al.[26] have postulated that when this indentation occurs the chordae attached to the posterior papillary muscle become slack, allowing the posterior mitral leaflet to balloon into the left atrium. Despite the segmental myocardial dysfunction the overall left ventricular performance is normal.[27]

The anatomic characteristics of the malformed mitral valve, with redundant leaflets and elongation of the chordae tendineae, have been observed at operation,[2,22] as in three of our cases. There are also pathologic descriptions,[28] including one[29] in which similar changes were observed in the tricuspid valve, as in our Case 2.

Etiology and natural history: Several possible origins of the lesion have been suggested, including rheumatic,[14] traumatic[7] or localized ischemic[25,30] heart disease. This type of valve abnormality also has been commonly seen in patients with Marfan's syndrome.[2,5,7,18] None of these possibilities were definable in our patients, thus supporting a congenital origin of the mitral valve abnormality.

Little is known about the natural history of a congenital balloon mitral valve identified in childhood, although adults have been found to have significant complications as a result of similarly malformed atrioventricular valves. Dysfunction of the mitral apparatus may produce insufficiency[30] that, once established, may become progressively severe.[31] Infective endocarditis has been reported in several instances,[3,29,32] indicating the need for proper antibiotic prophylaxis, even when the valve is competent.[33] Significant cardiac arrhythmias, particularly those related to exercise, have been reported in up to 50 percent of cases.[34,35] In some instances these have been presumed to be the cause of sudden death.[5,8] Thus, identification of a balloon mitral valve has important prognostic significance. Furthermore, the association of a balloon mitral valve with an ostium secundum atrial septal defect must be differentiated from an endocardial cushion defect (ostium primum atrial septal defect).

Clinical implications: Since we became acutely aware of this combination of defects we have routinely performed a left ventriculogram in all patients with atrial septal defect. Seven of 10 consecutive patients examined had a balloon mitral valve. In two adults (aged 19 and 21 years, respectively) and in Patient 8 of this study no abnormality of the mitral valve was suspected clinically since there were no unusual electrovectorcardiographic observations or suggestive apical auscultatory findings.

In summary, we conclude that every patient with an atrial septal defect should have a left ventriculogram to determine the status of the mitral valve.

Cyanosis and clubbing of the digits in patients with atrial septal defect usually are indicative of reversal of the interatrial shunt consequent to reduced right ventricular compliance and severe pulmonary hypertension. The condition may be considered inoperable. The cases reported herein emphasize the occurrence of cyanosis in patients with interatrial communication and continued significant left to right shunting, as a consequence of systemic venoarterial shunting into the left atrium. Carefully planned cardiac catherization is indicated to detect the less well recognized mechanisms of cyanosis so that such patients are not denied the benefits of surgical closure of the septal defect.

Cyanosis, clubbing of the digits and erythrocytosis in patients with an atrial septal defect generally result from shunting of venous blood through the interatrial communication. Since reduced distensibility of the right ventricle, the result of obstructive pulmonary hypertension, is responsible in most instances,[1] cyanosis may be considered to contraindicate operative treatment.[2] It is not widely recognized that arterial oxygen desaturation can occur in the presence of normal pulmonary vascular resistance and predominant left to right shunting as a consequence of functional or anatomic diversion of systemic venous return into the left atrium.[3,4] Under these circumstances, cyanosis does not constitute a contraindication to operative closure of the atrial septal defect. Our report therefore emphasizes this cause of venoarterial shunting in order that it may be more frequently considered and specifically sought during diagnostic cardiac catheterization.

Case Reports

Case 1. Atrial Septal Defect with Streaming of Inferior Vena Caval Blood Across the Defect into Left Atrium

Two years before admission a 55 year old telephone cable installer noted the onset of progressive dyspnea on exertion, a cough productive of clear sputum, and cyanosis of the nail beds. He denied chest pain, syncope or palpitations and had been unaware of any cardiac abnormality. He had smoked two packages of cigarettes daily for 20 years.

On physical examination, his face was plethoric and his lips and nailbeds were cyanotic. Neither his fingers nor his toes were clubbed. Blood pressure was 160/100 mm Hg, pulse rate 112/min and regular. Bilateral inspiratory rales were present. The cardiac apical impulse was palpated in the fifth left intercostal space in the midclavicular line. The second heart sound was widely split and remained split throughout the respiratory cycle. Subsequent phonocardiograms documented an increase in splitting of 15 msec during inspiration. Both atrial and ventricular diastolic gallops were audible. A grade 2/6 systolic ejection murmur was heard in the second left intercostal space; there was no diastolic murmur.

Hemoglobin was 19.2 g/100 ml and hematocrit 58 percent. Electrocardiograms revealed atrial tachycardia with 2:1 block resulting in a ventricular response of 100 beats/min; the mean QRS axis was vertical. Chest roentgeno-

Address for reprints: Joseph Lindsay, Jr., MD, The George Washington University Clinic, 2150 Pennsylvania Ave., N.W., Washington, D. C. 20037.

grams disclosed cardiomegaly, pulmonary plethora and diffuse nodular infiltrates. Values for arterial blood gases, obtained with the patient at rest and breathing room air, were as follows: PaO_2 58 mm Hg (87 percent saturation calculated), $PaCO_2$ 32 mm Hg, pH 7.46. With exercise, the PaO_2 increased to 62 mm Hg (93 percent saturation calculated). While the patient was breathing 100 percent oxygen, the PaO_2 rose only to 200 mm Hg (99.6 percent saturation calculated). A right to left intracardiac shunt was suspected.

During cardiac catheterization by way of the right femoral vein the catheter was easily advanced from the right atrium across an atrial septal defect to the left atrium. The left atrial angiogram revealed a left to right shunt in the central portion of the atrial septum. The hemodynamic data (Tables I and II) were interpreted as showing a bidirectional shunt at the atrial level. Hydrogen gas inhalation performed with platinum electrodes in the left pulmonary and left femoral arteries indicated the presence of a left to right shunt (Fig. 1). Ascorbate was injected sequentially into the pulmonary artery, right ventricle, right atrium and inferior vena cava. A small right to left shunt was demonstrated by the polarographic recording obtained from the femoral artery after inferior caval injection[5] (Fig. 2).

At operation, a 3 cm ostium secundum atrial septal defect was found and repaired with a Dacron® patch. The valve of the inferior vena cava (Eustachian valve) was not enlarged. Tissue obtained from lung biopsy was interpreted as showing chronic pleuritis, emphysema and septal fibrosis. On the first postoperative day, normal sinus rhythm returned. The ejection systolic murmur and the cyanosis disappeared postoperatively.

Comment: Pulmonary arterial pressure and resistance were near normal. Arterial hypoxemia may have been due in part to pulmonary disease since pulmonary venous saturation was only 93 percent. Nevertheless, additional right to left shunting across the atrial septal defect was confirmed by the ascorbate dilution study and detection of a further decline in oxygen saturation in blood obtained from the left ventricle and systemic arteries.

Case 2. Atrial Septal Defect with Shunting of Inferior Vena Caval Blood Into Left Atrium

A 40 year old laborer was well until age 16 years when, after an illness characterized by fever, myalgia and arthralgia, he noted a decrease in exercise tolerance. At age 21, exertional dyspnea occurred and physical examination revealed cyanosis, digital clubbing, fixed splitting of the second heart sound and a heart murmur. The diagnosis rendered at that time is not documented. Six years later these findings led to a diagnosis of atrial septal defect. Arterial hypoxemia was taken as evidence of Eisenmenger's syndrome, and the lesions were considered inoperable. Cardiac catherization was not performed.

The dyspnea increased in severity and at age 34, the patient experienced retrosternal chest pain relieved with nitroglycerin. He was hospitalized because of a prolonged episode of chest pain and given digoxin therapy. Between ages 34 and 40, he had several hospitalizations for recurrent chest pain. On the last of these diagnostic cardiac catheterization was performed.

At the time of admission for catheterization physical examination revealed cyanosis of the lips and nail beds and clubbing of the fingers. Blood pressure was 140/90 mm Hg and pulse rate 100/min with occasional premature ventricular contractions. The chest was clear to percussion and auscultation. The cardiac apical impulse was palpated in the fifth left intercostal space 2 cm lateral to the midclavicular line. A left parasternal impulse and a systolic pulsation in the third left intercostal space were present. The second heart sound was narrowly split and did not vary. A grade 2/6 systolic ejection murmur was audible in the second left intercostal space radiating along the left sternal border to the apex.

Cardiac catheterization was performed by way of the right median basilic vein. The catheter was easily advanced into two pulmonary veins entering the right atrium as well

TABLE I

Cardiac Catheterization Data

	Case 1	Case 2		Case 3

Calculated Indexes of Flow and Resistance

	Case 1	Case 2	Case 3
Pulmonary to systemic flow ratio	2.3/1	1.5/1	1.7/1
Left to right shunt as % of pulmonary blood flow	65%	50%	55%
Right to left shunt as % of systemic blood flow	25%	35%	25%
Pulmonary vascular resistance*	1.8†	6.4†	2.4

* $(\overline{PA} - \overline{LA})$/pulmonary blood flow (Wood's units).
† Normal oxygen consumption assumed in the calculation.

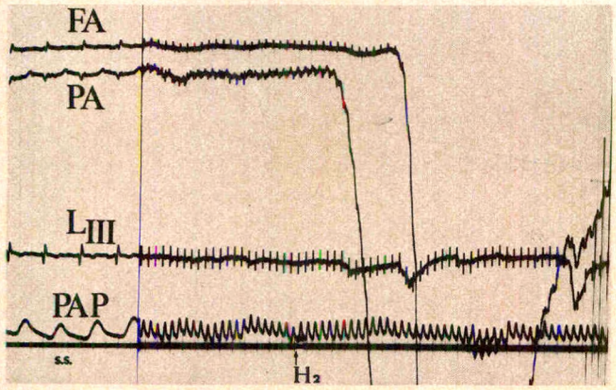

FIGURE 1. Case 1. Polarographic recordings from the femoral artery (FA) and pulmonary artery (PA) after inhalation of hydrogen gas (H_2). The hydrogen is first detected by the pulmonary arterial electrode indicating a left to right shunt. L_{III} = lead III of the electrocardiogram; PAP = pulmonary arterial pressure.

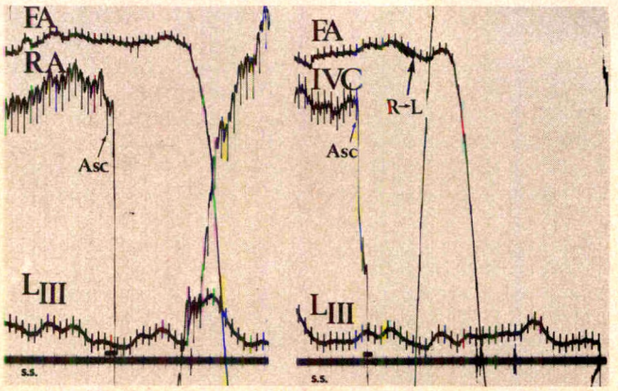

FIGURE 2. Case 1. Polarographic recordings from the femoral artery (FA) after injection of ascrobate (Asc) into the right atrium (RA) and inferior vena cava (IVC). A right to left (R → L) shunt is only seen after injection into the inferior vena cava.

as across an atrial septal defect to the left atrium. Indicator-dilution curves were performed. Blood was drawn from the brachial artery after injections of indocyanine green into both the inferior and the superior venae cavae. The curve obtained after injection into the inferior vena cava revealed two peaks, an early peak at 6 1/2 seconds and a late peak at 15 1/4 seconds; the curve obtained after injection into the superior vena cava disclosed only the late peak at 15 3/4 seconds (Fig. 3). These curves are consistent with shunting of blood from the inferior vena cava, but not the superior vena cava, into the left atrium. Inferior vena caval angiography with injection of the contrast media at the junction of the inferior vena cava and right atrium confirmed this streaming into the left atrium.

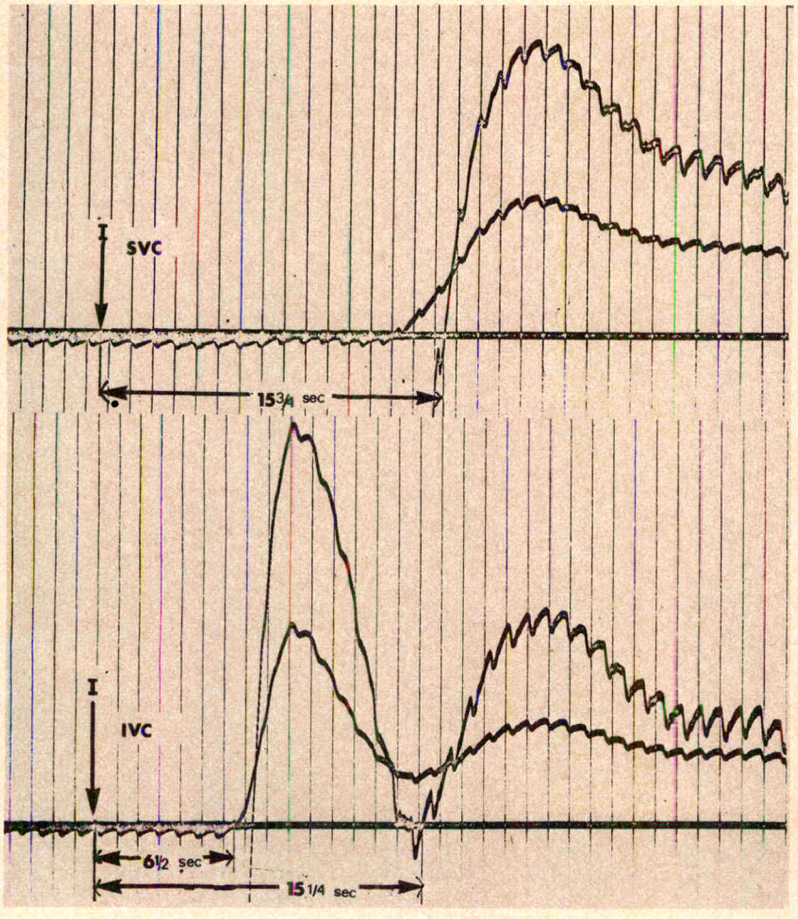

FIGURE 3. Case 2. Indicator-dilution curves recorded from the brachial artery after injection (I) of indocyanine green into the superior vena cava (SVC) **(top)** and the inferior vena cava (IVC) **(bottom).** The taller of each set of curves is the semilogarithmic replot; the smaller curve is the linear recording. See text for details.

Pressure measurements were made, oxygen saturation levels determined (Table I) and flow and resistance values calculated (Table II). The data were interpreted as indicating a bidirectional interatrial shunt and severe pulmonary hypertension. Results of coronary arteriography and left ventriculography performed 1 week later were normal.

At operation, a 3 by 4 cm ostium secundum atrial septal defect associated with two pulmonary veins draining anomalously into the right atrium was found. The valve of the inferior vena cava was not abnormally large. The atrial septal defect was repaired with a Teflon® patch, and the anomalous pulmonary veins were directed into the left atrium.

The murmur and cyanosis disappeared postoperatively. Repeat cardiac catheterization was performed 3 months later. By means of hydrogen inhalation a small residual left to right interatrial communication was documented. Pulmonary arterial pressure had declined, but calculated pulmonary resistance was unchanged (Tables I and II).

Comment: The patient's prognosis is believed to be improved by operation although the long-term response of the pulmonary circulation is not known.

Case 3. Atrial Septal Defect with Persistent Left Superior Vena Cava Entering Left Atrium

A 48 year old itinerant burlesque comedian was admitted because of congestive heart failure and syncope. He had been told that he was cyanotic at birth. He experienced brief episodes of palpitations during childhood but denied any exercise limitation. At age 28 years, when a heart murmur was first heard, he was asymptomatic.

Cardiac catheterization was performed in another city 8 months before his present admission because of congestive heart failure and atrial fibrillation. The catheterization was performed by way of the right femoral artery and vein with use of the percutaneous technique. The venous catheter was easily advanced from the right atrium across an atrial septal defect into the left atrium. Pressures were measured, oxygen saturation levels determined (Table I) and values for flow and total pulmonary resistance calculated (Table II). These measurements were interpreted as indicating a predominant left to right shunt, a smaller right to left shunt, pulmonary hypertension and increased ventricular end-diastolic pressure.

After treatment with digoxin, diuretic agents and a low salt diet, the patient's condition improved, but 4 months before his present admission, after a period of dietary indiscretion, the congestive heart failure worsened and he had syncope for the first time. He was appropriately treated for heart failure and again became asymptomatic. One week before his present admission, he noted increased symptoms of congestive heart failure and on the day of admission he had a syncopal episode.

Physical examination revealed clubbing of the fingers and cyanosis of the lips and nail beds. Blood pressure was 120/70 mm Hg and pulse rate 80/min and irregular; respiratory rate was 25/min. Jugular venous distension was present to the angle of the mandible with the patient seated upright; prominent *v* waves were seen. Inspiratory rales were heard over both lung fields. The cardiac apex impulse was palpated in the fifth left intercostal space at the anterior axillary line. A left parasternal impulse was present. The second heart sound was physiologically split. A pansystolic murmur that increased in intensity during inspiration was audible at the lower left sternal border and radiated to the apex; a systolic ejection murmur was heard in the second left intercostal space. The liver span was 20 cm by percussion in the midclavicular line, and the spleen tip was palpable. Pitting edema and stasis dermatitis were present in both legs.

Hemogram revealed leukocyte count 3,000 cells/mm^3 with a normal differential; hemoglobin was 12.7 g/100 ml and hematocrit 39.0 percent. Values for arterial blood gases were pH 7.48, $PaCO_2$ 37 mm Hg, PaO_2 55 mm Hg (89 percent saturation calculated). Chest roentgenograms disclosed cardiomegaly, enlarged pulmonary arteries, an inconspicuous aortic knob and bilateral alveolar and interstitial infiltrates. Electrocardiograms revealed right bundle branch block, right axis deviation, right ventricular hypertrophy and atrial fibrillation.

The congestive heart failure was treated with digoxin, furosemide and oxygen. The patient was given anticoagulant therapy because of a clinical diagnosis of pulmonary emboli. The hospital course was downhill, and he died on the 12th hospital day after having major seizures and becoming aphasic.

Postmortem examination revealed a large atrial septal defect involving the posterior aspect of the atrial septum, a persistent left superior vena cava entering the left atrium, and absence of the coronary sinus. The heart weighed 950 g, and there was biatrial and biventricular hypertrophy.

Comment: The patient's life style prevented his obtaining appropriate medical care until the situation was far advanced. Operation was not contraindicated and might have been helpful had it been undertaken after cardiac catheterization 8 months before death. The onset of cyanosis in infancy was no doubt due to the venoarterial shunting from the anomalous systemic venous connection to the left atrium.

Discussion

In 1949 Selzer and Lewis[6] called attention to patients with atrial septal defect who had cyanosis unassociated with pulmonary hypertension or pulmonic stenosis. Reporting on 12 such patients, 2 with cyanosis since birth, they postulated functional drainage of systemic venous blood into the left atrium as the mechanism of cyanosis. Their conclusion was supported by the dye-dilution studies of Swan et al.,[7] which detected right to left shunting of small amounts of caval blood through interatrial communications in certain patients with a predominant left to right shunt. The quantity of such mixing usually did not result in clinical cyanosis.

Renewed interest in the anatomy of the right atrium generated by the introduction of surgical techniques to repair atrial septal defects led to the recognition of certain anatomic variations that appear to favor passage of inferior vena caval inflow into the left atrium.[8,9] Persistence of a large right valve of the sinus venosus (valve of the inferior vena cava, Eustachian valve) was shown to result in the deflection of a sufficient volume of venous blood into the left heart chambers to produce clinical cyanosis.[3] Others observed that the lower rim of ostium secundum defects was at times deficient. As viewed at operation this situation, attributable to excessive resorption of the ostium primum, was characterized by apparent continuity of the medial wall of the inferior vena cava with the inferior wall of the left atrium and by overriding of the caval inflow by the atrial septum.[9] Although

cases documenting clinical cyanosis from this abnormality have not to our knowledge been reported, it appears to be a possible mechanism.

In our two patients who were operated on, these anatomic aberrations were not detected. Neither were they reported by Winters et al.[10] in their description of two instances of cyanosis in patients with atrial septal defect, cyanosis and rather normal right heart pressures. Their cases and ours suggest that other anatomic alterations may account for cyanosis in some of these patients. Moreover, reduced right ventricular compliance not severe enough to result in balanced or reversed shunting may favor this pattern of flow in instances with unrecognized subtle structural peculiarities.

Our third case appears to be an example of a rare entity described by Raghib et al.[4] They described a developmental triad consisting of a persistent left superior vena cava terminating in the left atrium, absence of the coronary sinus, and an atrial septal defect involving the posteroinferior angle of the atrial septum. They attributed the three coexisting anomalies to failure of complete formation of the left atrioventricular fold, the fold that normally develops along the left side of the junction of the sinus venosus and the atrial portion of the heart.

Our three cases are additional examples of the occurrence of cyanosis despite persistent significant left to right shunting. In two patients streaming of the inferior caval blood across the atrial defect probably accounted for the venoarterial shunting. Altered right ventricular compliance may have been a factor favoring such a flow pattern in Case 2. The third case exhibited a rather rare type of congenital anomalous venous connection that resulted in the return of venous blood to the left atrium. We thus emphasize that the presence of cyanosis in patients with atrial septal defect cannot be used as infallible evidence of balanced or net right to left shunting, thereby constituting a contraindication to surgical closure of the defect. Carefully planned cardiac catheterization is indicated to detect the less well known mechanisms of cyanosis.

Acknowledgment

We thank George A. Kelser, Jr., MD for allowing us to include Case 1. We also appreciate the generosity of A. A. Douglas Moore, MD of Norfolk, Va. in providing the cardiac catheterization data in Case 3.

Patency of Aortocoronary Vein Grafts and Serum Triglycerides

Three Year Follow-Up Study

CLAUDE ALLARD, PhD
CLAUDE GOULET, MD, FACC
CLAUDE M. GRONDIN, MD
JACQUES LESPERANCE, MD
MARTIAL G. BOURASSA, MD

Montreal, Quebec, Canada

Fasting blood lipid levels were determined before operation and 1 and 3 years after operation in 36 patients to verify the hypothesis that hypertriglyceridemia plays a role in the fate of aortocoronary vein grafts. Graft patency was evaluated with use of arteriography 2 weeks, 1 year and 3 years after operation. Results of these studies show that patients with hypertriglyceridemia have a higher risk of occlusion or stenosis of vein grafts. Serum cholesterol levels do not appear to affect the fate of the grafts.

Serum triglyceride concentration was correlated with the fate of aortocoronary vein grafts 2 weeks and 1 year after operation in previous studies from our laboratory.[1] The findings suggested that triglyceride levels play an important role in the occlusion or reduction of the caliber of vein grafts. In this investigation we attempted to verify this hypothesis in 36 patients who had serial lipid analyses and angiographic evaluations before operation and 1 and 3 years after operation. If the hypothesis is valid, a low level of triglycerides should be associated with long-term patency of the grafts. Our current data appear to strengthen this hypothesis.

Subjects and Methods

In the first study, 163 consecutive patients had blood lipid determinations and selective angiography 2 weeks after operation, and 82 were similarly studied 1 year later.[1] Of these 82 patients, 36 were restudied 3 years postoperatively and form the basis of this study. Seventeen of these patients had multiple grafts, and 19 had single grafts. These 36 patients are part of a larger series of patients studied angiographically 3 years postoperatively by Grondin et al.[2] and Lespérance et al.[3] The latter two studies demonstrated that no vein graft was further reduced in caliber between the 1st and 3rd years after operation and only 5 percent became occluded in this period. Thus, the 36 subjects described here probably represent a valid sample of the larger groups.[2,3]

Arteriography was performed by the technique described previously.[4] Fasting blood samples were collected on the morning of the angiographic studies before operation and 1 and 3 years after operation. Total serum cholesterol and triglycerides were assayed as in the previous report.[1]

Results

Of the 36 patients, 1 had occlusion of a single graft 3 years postoperatively. In 27 of the remaining 35 patients, no occlusion occurred in their single or multiple grafts. Eight patients with multiple grafts had occlusion in one graft 1 year postoperatively. Table I shows the mean serial triglyceride concentration for all patients studied. The triglyceride level was lower 1 year postoperatively than before operation ($P < 0.05$), as in the previous report.[1] This difference was believed to be secondary to a loss of weight.[1] The triglyceride values at 1 and 3 years were not significantly different. The triglyceride levels of patients with single and multiple grafts did not differ significantly in any of

the three studies. Table II shows that the mean concentration of triglycerides for all patients in all three studies was 203 ± 91 (standard deviation) mg/100 ml.

In the 27 patients whose grafts remained patent during the 3 year period, this mean value was 186 ± 82 mg/100 ml (Table II). The cholesterol level in these patients did not change during the 3 year period and was 246 ± 57 mg/100 ml at 3 years (Table III).

Discussion

Occlusion of aortocoronary vein grafts is uncommon between 1 and 3 years after operation, and little or no reduction occurs in the diameter of the graft.[2,3] This finding is in sharp contrast with the relatively high rate of occlusion and the diffuse reduction in the caliber of the graft noted 1 year postoperatively. It has been shown[2] that in patients whose grafts are occluded 2 weeks after operation, the mean triglyceride level is higher (287 mg/100 ml) than that (235 mg/100 ml) of patients whose grafts are occluded later, 1 year after operation. The same study also demonstrated that the mean triglyceride level was significantly lower (181 mg/100 ml)[1] in patients who had patent grafts with little or no reduction of caliber at 1 year.[1] In our study, patients whose grafts were patent 3 years postoperatively had an overall mean triglyceride level of 186 ± 82 mg/100 ml (Table II).

Patients with the lowest serum triglyceride levels demonstrated patency of all their grafts in each of the three angiographic studies, and our findings suggest that patients with high triglyceride levels may be at greater risk of occlusion or stenosis of vein grafts during the first year after operation. This notion of risk implies that other factors[1,3,4] play a role in the fate of the vein graft. These factors may include the surgical technique itself, the quality of the artery grafted (diameter, degree of atherosclerosis, runoff) and the presence of stenosis at the site of anastomoses. The occlusion of grafts or the progressive reduction in their caliber may perhaps be prevented or minimized by a better selection of patients[5] and by improved surgical technique.[6] However, our results suggest that hypertriglyceridemia is a factor that should be taken into consideration and corrected. Patients may benefit from a reduction in serum triglycerides before and after myocardial revascularization. The possible mechanisms by which hypertriglyceridemia influences the fate of the aortocoronary vein grafts has been discussed previously.[1]

Chordae Tendineae Rupture Complicating the Systolic Click-Late Systolic Murmur Syndrome

DORIS GOODMAN, MD, FACC
DEMETRIOS KIMBIRIS, MD, FACC
JOSEPH W. LINHART, MD, FACC

Philadelphia, Pennsylvania

In a patient with a documented nonejection systolic click and late systolic murmur, acute mitral insufficiency developed as a result of spontaneous rupture of mitral chordae tendineae. There was no evidence of previous endocarditis, rheumatic fever or congenital heart disease. The ballooning mitral valve syndrome has previously been considered relatively benign. Chordal rupture has been predicted, and presumptive cases have been alluded to by several investigators. This well documented report of such a complication casts further doubt on the benignity of the syndrome.

The prognosis of patients with a mid-systolic click and late systolic murmur due to abnormalities of the mitral valve apparatus was initially thought to be benign. A number of complications are now known to occur in these patients, casting considerable doubt upon the benignity of the lesion. Spontaneous chordal rupture with resulting acute severe mitral insufficiency has been predicted in this syndrome[1–4] but, although alluded to in several reports,[5,6] this complication is not generally well known and the clinical course has not been documented. In this report we document the development of acute mitral insufficiency due to ruptured chordae tendineae in an asymptomatic patient with the nonejection systolic click-late systolic murmur syndrome; the condition resulted in severe congestive heart failure requiring urgent surgery. The rapid evolution of this severe hemodynamic disturbance emphasizes one of the potential serious complications of this syndrome.

Case Report

A 52 year old woman consulted a cardiologist in 1967 because of chest pain of the anginal type. The symptoms had been mild and infrequent, occurring only three to four times a year in relation to stress or fatigue. She had been taking coronary vasodilating agents and had been able to work as a clinic nurse without difficulty. Years previously she had been given procainamide for troublesome palpitations which had subsided spontaneously. She had knowledge of a heart murmur since age 23 but had no history of rheumatic fever. Physical examination at this time was noncontributory except for a prominent mid-systolic click and a grade 2/6 late systolic murmur heard at the apex. There was no evidence of cardiac enlargement or congestive heart failure. Subsequently she continued to take coronary vasodilating agents, and the click and murmur were heard at each of approximately 12 examinations during the next 5 1/2 years by the same observer. Periodic electrocardiograms were essentially normal and did not change.

In December 1971 left lingular pneumonia developed with pneumococcus isolated from sputum, and negative blood cultures. Her attending internist noted the cardiac findings and phonocardiography was performed (Fig. 1). She made an uneventful recovery, and auscultatory findings continued unchanged.

In March 1973 at age 58, she had fever of 102° F and a cough producing thick yellow blood-streaked sputum. Chest X-ray films showed extensive infiltrate fanning out from the right hilum involving the right middle and lower

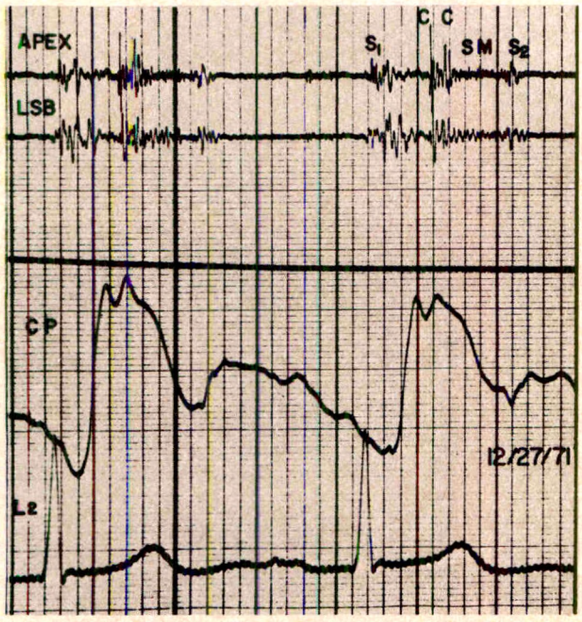

FIGURE 1. Phonocardiogram recorded at the apex and left sternal border (LSB) in December 1971 during an episode of bronchopneumonia. A double nonejection systolic click (C) is present, followed by a late systolic murmur (SM). CP = carotid arterial pulse; L_2 = lead II of the electrocardiogram.

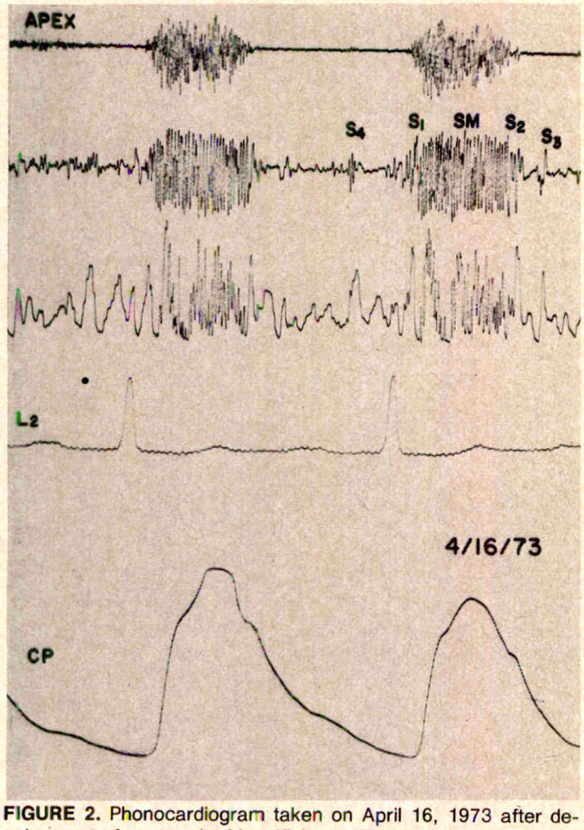

FIGURE 2. Phonocardiogram taken on April 16, 1973 after development of acute mitral insufficiency. The murmur (SM) is now pansystolic, and there are prominent atrial (S_4) and ventricular (S_3) gallops.

pulmonary lobes, consistent with bronchopneumonia. Physical examination revealed a dramatic change in the murmur, which was now grade 6/6, pansystolic, blowing and radiating widely throughout the precordium and to the back, accompanied by a systolic thrill. A loud ventricular third sound gallop was present, and the systolic click was no longer heard. There were no stigmata of bacterial endocarditis at this time or subsequently and results of five blood cultures were negative. Sputum culture grew no pathogens. Peripheral blood examination showed only mild leukocytosis and no leftward shift. Results of lung radioisotope scan were consistent with pneumonia or pulmonary embolism, or both. The electrocardiogram now showed a rightward shift of the electrical axis and probable left ventricular hypertrophy.

Treatment with antibiotic agents and heparin was started, and digitalis and diuretic agents were given because of the development of congestive heart failure and atrial fibrillation. She rapidly became afebrile, had a significant diuresis and the atrial fibrillation reverted to normal sinus rhythm. The murmur and gallop remained loud after discharge, however, and she was readmitted for further studies because of marked respiratory distress including paroxysmal nocturnal dyspnea.

Phonocardiography confirmed the pansystolic murmur and the atrial and ventricular gallops (Fig. 2). *Cardiac catheterization* data were consistent with acute mitral insufficiency, revealing an increased mean wedge pressure of 30 mm Hg, massive *V* waves of 60 mm Hg and pulmonary hypertension. Angiograms disclosed slight enlargement of the left ventricle and left atrium with 4+ mitral regurgitation. The posterior leaflet of the mitral valve was thin, not calcified and very mobile, ballooning into the left atrium during systole (Fig. 3). The aortic valve and right and left coronary arteries were normal.

Mitral valve replacement was undertaken because of persistent class IV (New York Heart Association classification) symptoms despite intensive medical therapy. At operation, the mitral valve leaflets were intact, smooth, thin and mobile with no lesions suggesting previous endocarditis. Three avulsed chordae to the central portion of the posterior leaflet were noted. The mitral valve was replaced with a Cooley-Cutter prosthesis. Postoperatively hypoten-

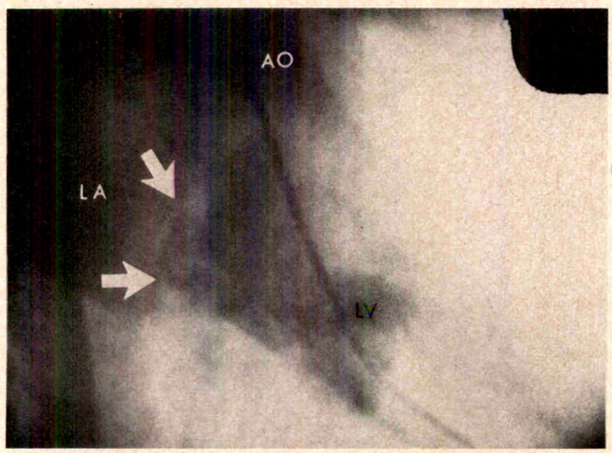

FIGURE 3. Left ventricular angiogram in right anterior oblique projection. The posterior mitral valve leaflet is seen ballooning into the left atrium (LA) during systole **(arrows).** The left atrium is heavily opacified as a result of the massive mitral regurgitation. AO = aorta; LV = left ventricle.

sion and severe bradycardia developed. Reoperation was attempted to control bleeding after medical measures had failed, but the patient died.

Autopsy findings disclosed no additional congenital or acquired heart defects, stigmata of endocarditis or evidence of healed rheumatic heart disease. Special staining of leaflet tissue did not show myxomatous or mucoid changes.

Two of the patient's five children were examined and one, a 27 year old daughter, had a systolic click and murmur documented by phonocardiography.

Discussion

The syndrome of the systolic click-late systolic murmur has been recognized for at least a decade. Diverse causes have been postulated for the mild mitral insufficiency, including rheumatic fever, healed endocarditis, trauma, connective tissue disorders, atheromatous involvement of leaflets and chordae, cardiomyopathy and ischemic papillary muscle dysfunction.[1,7–12] In many patients no underlying cause is demonstrable, but hemodynamic and pathologic evidence for the valvular and chordal dyskinesis has been demonstrated by an abnormally large mitral annulus,[9,12,13] asynergy of left ventricular contraction[10,13,14] and a ground substance abnormality in the valve leaflet.[15] A familial occurrence is also well documented.[9,10,16–19]

Prognosis: Patients with auscultatory findings of prolapsing mitral valve leaflets and mild mitral insufficiency without other complicating heart disease have been thought to have a relatively good prognosis. Segal and Likoff[20] studied eight patients with mild exertional dyspnea and rapid irregular heartbeat and concluded that the click-murmur syndrome was innocent. Engle[12] stated that the syndrome was benign although the patients she described had T wave abnormalities on the electrocardiogram. Hancock and Cohn[7] described 40 patients with the syndrome, some of whom complained of palpitations, mild dyspnea and atypical chest pain. These investigators documented atrial and ventricular arrhythmias in several patients and an R on T phenomenon in one patient who died suddenly. They concluded that the prognosis was favorable except in patients with arrhythmias.

Barlow et al.[2] alluded to sudden death in patients with abnormal electrocardiograms and arrhythmias and stated the prognosis must be guarded in such patients. Gooch et al.[14] and Pocock and Barlow[9,22] commented on the emergence of serious arrhythmias after exercise testing in patients with the syndrome, and considered suppression of the arrhythmias important enough to warrant use of antiarrhythmic drugs.

Potential complication of chordal rupture and acute mitral regurgitation: Streptococcus viridans endocarditis has been reported in patients with the click-murmur syndrome[7,17,23] and in a patient with only a click who had a transient late systolic murmur during the acute phase of the infection,[24] and antibiotic prophylaxis was recommended on this basis. However, Stannard et al.[16] in describing 13 patients with no symptoms of cardiac decompensation noted that the majority had had teeth extracted without developing bacterial endocarditis. Criley et al.[1] and Barlow et al.[2] predicted that the minimal mitral regurgitation might be self-perpetuating and might progress after many years to severe valvular incompetence with or without ruptured chordae, on the principle that mitral insufficiency begets mitral insufficiency. Cobbs[3] stated that despite lack of suitable linear follow-up studies, patients with the syndrome constitute a significant reservoir for spontaneous chordal rupture developing after two or more decades.

Singh et al.,[4] citing seven patients with spontaneous rupture of mitral chordae tendineae, mentioned two who had apical systolic murmurs for several years before the onset of acute mitral insufficiency. They stated that the long-term prognosis of the recently characterized floppy mitral valve syndrome was not sufficiently known to predict whether there would be a high rate of late spontaneous chordal rupture. Leachman and Cokkinos[5] described 19 patients operated upon for mitral regurgitation and found to have rupture of chordae to the posterior leaflet; 4 of these had a murmur dating from childhood or young adulthood and may have had a syndrome similar to that of our patient. These authors stated that the main complication of the syndrome seems to be its tendency to progress to massive mitral regurgitation due to chordal rupture, but they provided no documentation of prior and later findings constituting suitable linear follow-up of this lesion. Sloman et al.[6] followed up 50 patients with the syndrome and found 2 who had progressive regurgitation requiring surgery. Both had "flail" posterior mitral valve leaflets and ruptured chordae, and the authors postulated that the primary leaflet abnormality with secondary excessive chordal tension might be the predisposing cause of rupture.

In our patient we had clear clinical evidence of acute mitral insufficiency and searched for valvular perforation or chordal disruption, or both, by endocarditis as the most likely cause. Our patient had no laboratory or pathologic evidence for infection and no history or stigmata of a remote rheumatic process. Her prominent auscultatory pattern of ballooning mitral valve syndrome had been heard repeatedly and documented by phonocardiography before her acute cardiac decompensation.

We conclude that spontaneous rupture of chordae tendineae developed at the time of the acute febrile illness, with rapid progression from hemodynamically insignificant late mitral insufficiency to severe valvular regurgitation due to loss of chordal support to the posterior mitral valve leaflet. The carefully documented course of our patient leaves no doubt that the previously reported benignity of the systolic click-late systolic murmur syndrome is in question. The case emphasizes the serious potential complication of chordal rupture, in addition to the previously reported instances of not-so-benign fatal cardiac arrhythmias and bacterial endocarditis.

Diastolic Blood Flow into the Pulmonary Artery in Carcinoid Heart Disease

PAUL M. WOLFSON, DO
LOTFY L. BASTA, MD
RICHARD P. SNODGRASS, MD
J. MICHAEL KIOSCHOS, MD

Iowa City, Iowa

A patient with carcinoid heart disease manifested by mild pulmonary stenosis, severe tricuspid incompetence and mild tricuspid stenosis had unequivocal evidence of blood flow from the right ventricle into the pulmonary artery during ventricular diastole. Simultaneous right ventricular and pulmonary arterial pressure curves demonstrated that right ventricular diastolic pressure exceeded pulmonary arterial pressure during mid-diastole, indicating consistent mid-diastolic opening of the pulmonary valve. This was followed by a parallel increase in right ventricular and pulmonary arterial pressures throughout the rest of diastole. Right heart cineangiograms, obtained with right atrial dye injection, substantiated the pattern of flow from the right ventricle to the pulmonary artery during ventricular diastole. This previously unrecognized phenomenon is probably due to the combined effects of increased right atrial pressure, decreased right ventricular compliance and normal pulmonary arterial pressure.

Ordinarily there is no blood flow from the right ventricle to the pulmonary artery during ventricular diastole. However, such flow is theoretically possible in diseases characterized by increased right atrial pressure and decreased pulmonary arterial pressure, particularly if associated with a noncompliant right ventricle. This combination is typically encountered in carcinoid heart disease. Under such circumstances opening of the tricuspid valve will lead not only to right ventricular filling but also to blood flow into the pulmonary artery during ventricular diastole because of the existing right atrial-right ventricular-pulmonary artery diastolic gradient.

The cardiac lesions in carcinoid syndrome consist of endocardial fibrous plaques involving the pulmonary valve, tricuspid valve, right atrium, right ventricle, cardiac veins and, less commonly, the left heart chambers.[1–5] The most common hemodynamic sequelae are pulmonary valve disease, usually with mild stenosis, accompanied by tricuspid valve disease with predominant incompetence. Hemodynamic and angiographic data are available in a few patients with carcinoid heart disease, but there has been no mention of forward flow into the pulmonary artery during diastole in any of the reported cases. Recently, we observed a patient with unequivocal evidence of blood flow from the right ventricle to the pulmonary artery during diastole.

Case Report

A 45 year old Caucasian woman was evaluated at the University of Iowa Hospitals in February 1973 because of progressive fatigability, ankle edema, a 20 lb weight gain and an increase in abdominal girth during the preceding 9 months. The patient enjoyed perfect health until 3 years earlier when she noted attacks of watery diarrhea without abdominal cramping or urgency. Gastrointestinal examination and tests at that time revealed no abnormality, and the condition was diagnosed as functional bowel syndrome. Two years

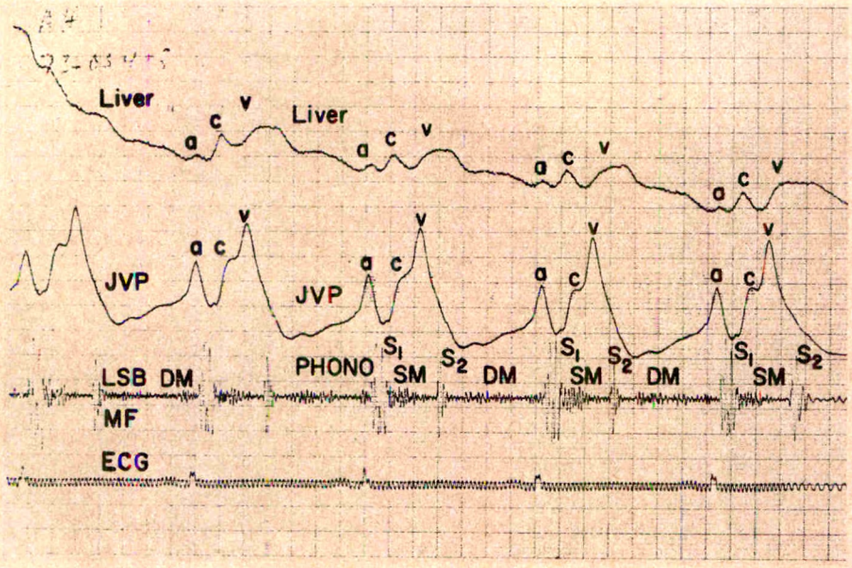

FIGURE 1. Simultaneous recordings of hepatic pulsations, jugular venous pulsations (JVP), phonocardiogram (PHONO) at left lower sternal border (LSB) and electrocardiogram (ECG). DM = diastolic murmur; MF = medium frequency; SM = systolic murmur.

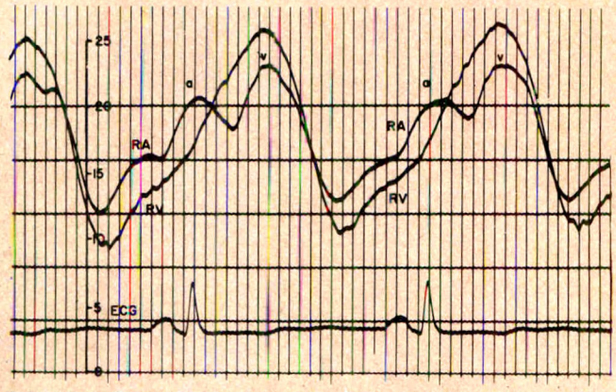

FIGURE 2. Simultaneous right atrial (RA) and right ventricular (RV) pressure tracings. Note the similar systolic wave form in both tracings, the diastolic atrioventricular gradient and the prominent *A* wave in the right atrial pressure tracing.

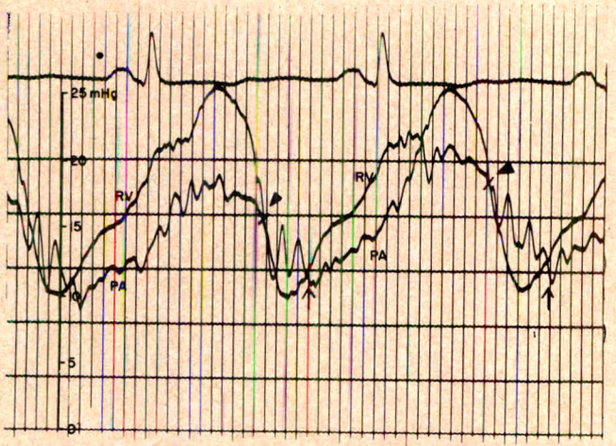

FIGURE 3. Simultaneous right ventricular (RV) and pulmonary arterial (PA) pressure tracings. Note the timing of pulmonary valve closure **(arrowhead)** and the diastolic opening of the pulmonary valve **(arrow)**, after which the increase in pulmonary pressure parallels that in right ventricular diastolic pressure.

later she noted minor daily flushing which she attributed to impending menopause; the flushing was not related to exertion, meals or excitement. The patient did not experience wheezing. No cardiac murmurs had been noted previously.

Examination revealed an alert woman in no distress, a regular pulse of 72 beats/min, blood pressure of 124/76 mm Hg, and a jugular venous pressure of 20 cm water with prominent *A* and *V* waves (Fig. 1). Carotid and peripheral pulses were normal. Cardiac examination revealed no left ventricular enlargement, a diastolic and a gentle early systolic left parasternal impulse, normal heart sounds, a grade 2/6 systolic murmur and a grade 2/6 diastolic rumble heard at the left lower sternal border (Fig. 1). Both murmurs increased with inspiration. The liver was tender and pulsatile and had a span of 15 cm in the right midclavicular line. The spleen was not palpable and there was questionable ascites. Both legs showed distal tense, brawny edema. Laboratory data revealed mild normocytic anemia, normal functioning of the liver and kidney and normal serum protein values. Twenty-four hour urinary 5-hydroxyindolacetic acid values were 98 and 127 mg in two collections (normal <10 mg). An electrocardiogram showed nonspecific ST–T changes and the chest X-ray films were noncontributory. A filling defect in the terminal ileum was seen on intestinal roentgenograms, and a liver radioisotope scan showed multiple filling defects.

Cardiac catheterization was performed because the patient's disabling symptoms were almost entirely cardiac in origin and tricuspid valve replacement was being considered. Simultaneous right atrial and right ventricular pressure curves (Fig. 2) and simultaneous right ventricular and pulmonary arterial pressure curves (Fig. 3) were obtained using catheters of equal bore diameter (no. 6F) and length and equisensitive simultaneously calibrated transducers. Reversing catheter connections yielded identical tracings. Hemodynamic findings (Table I) indicated a low cardiac index, normal pulmonary arterial pressure, mild pulmonary and tricuspid valve stenosis but normal left ventricular findings. Simultaneous pressure tracings showed reduced right ventricular pressure compared to pulmonary arterial pressure in early diastole, but soon thereafter right ventricular pressure exceeded pulmonary arterial diastolic

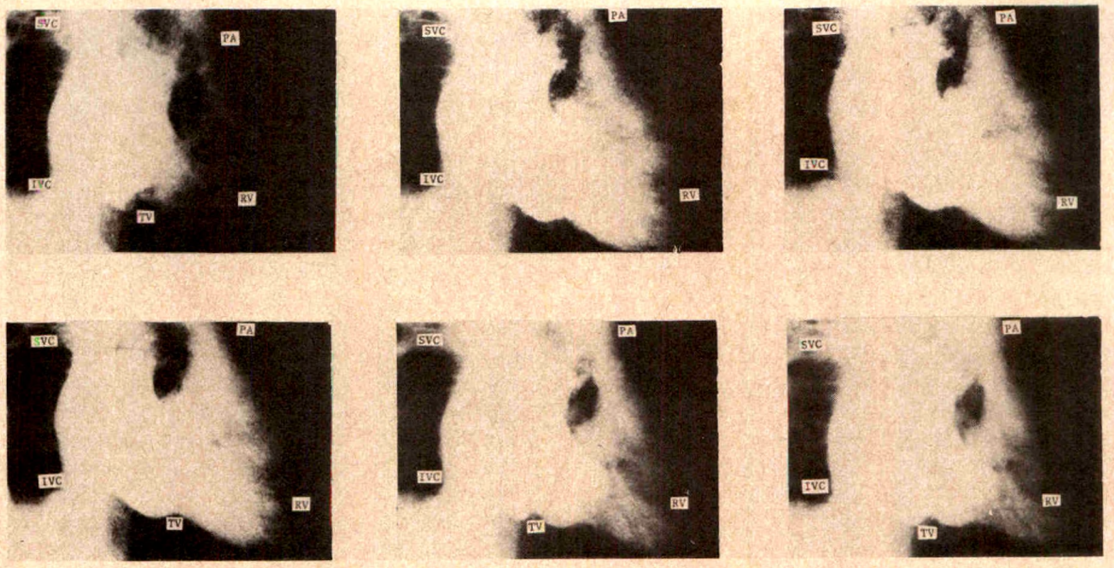

FIGURE 4. Cineangiographic frames obtained by dye injection into the right atrium. **Upper row,** during ventricular diastole (frames 1, 8, 15); **lower row,** during ventricular systole (frames 22, 29, 32). Note the flow of dye into the pulmonary artery during ventricular diastole. Cineangiograms filmed at 32 frames/sec. Heart rate during injection 64 beats/min. IVC = inferior vena cava; PA = pulmonary artery; RA = right atrium; RV = right ventricle; SVC = superior vena cava.

pressure, thereby indicating pulmonary valve opening at a pressure of 12 mm Hg (Fig. 3). For the rest of diastole pulmonary arterial pressure increased in parallel with the pressure rise in the right atrium and ventricle. Using a no. 8 angio-catheter, 60 ml of Renografin-76® was injected into the right atrium at a rate of 20 ml/sec and cineangiograms were filmed at a rate of 32 frames/sec in the right anterior oblique projection using a Phillips 9 inch image intensifier. Injection of dye into the right atrium produced opacification of that chamber. With the opening of the tricuspid valve in ventricular diastole, there was prompt opacification of the right ventricle and, within a small fraction of a second, the pulmonary artery, distinctly before the onset of ventricular systole (Fig. 4).

The day after cardiac catheterization, the patient suddenly collapsed upon arising from bed. Nausea and vomiting developed, as well as an intense cutaneous flush and generalized edema. The blood pressure became imperceptible. Her condition improved gradually with rapid intravenous administration of saline solution. Subsequently she has had several severe attacks of flushing, mainly related to standing. Methylprednisone was not of substantial help, but the noncardiac manifestations of disease responded favorably to a combination of antineoplastic agents (streptozotocin and 5-fluorouracil). Cardiac surgery has been deferred but may need to be reconsidered if the patient's chief symptoms continue to be related to cardiac involvement.

Discussion

In our patient, right ventricular to pulmonary artery blood flow during ventricular diastole was demonstrated by simultaneous right ventricular and pulmonary arterial pressure curves, as well as by right heart cineangiograms utilizing right atrial dye injection. Although this phenomenon has not been emphasized previously, available data in reported cases of carcinoid heart disease strongly suggest a similar hemodynamic situation in some of these patients.[5–8]

TABLE I

Hemodynamic Findings

Variables	Values
Pressures (mm Hg)	
Right atrial (RA)	$a = 21$, $v = 23$ (18)
Right ventricular (RV) systolic/end-diastolic	26/18
Pulmonary arterial (PA)	22/10 (14)

Left ventricular volumes (ml)	
End-diastolic	88
End-systolic	33
Ejection fraction	0.62

Figures in parentheses indicate mean values.

Four of 11 patients studied by Trell et al.[5] and the patient described by Wright and Mulder[6] had right ventricular end-diastolic pressure greater than the corresponding pulmonary arterial diastolic pressure. The patient described by Levine and Folse[7] and that by Rokseth and Sanderud[8] had right ventricular pressure curves very similar to those of our case, but simultaneous recordings with pulmonary arterial pressure are not available in these patients.

The association of this phenomenon with carcinoid heart disease may be related to a combination of factors including: (1) increased right atrial pressure due to the added effects of severe tricuspid regurgitation, relatively mild tricuspid stenosis and decreased right atrial compliance, (2) decreased right ventricular compliance due to subendocardial fibrosis, and (3) normal pulmonary arterial pressure. It is possible that blood flow into the pulmonary artery during diastole occurs not only in carcinoid heart disease but also in conditions characterized by increased right atrial pressure and normal pulmonary arterial pressure, such as Ebstein's disease and other congenital or acquired anomalies of the tricuspid valve. It has been shown that pulmonary arterial pressure tracings in patients with Ebstein's disease may show a presystolic positive wave coincident with atrial contraction,[9] which suggests presystolic blood flow into the pulmonary artery.

Theoretically, angiographic evidence of blood flow from the right atrium to the right ventricle to the pulmonary artery during diastole in our patient might have been augmented artifactually by an increase in atrial pressure caused by the injection of dye into the right atrium. Although data on atrial pressure were not obtained in our patient, in our laboratory right atrial injection by the method used in this study has not increased mean right atrial pressure by more than 3 mm Hg, nor has it altered pulmonary arterial pressure significantly. Furthermore, the angiographic findings in our case were consistent with hemodynamic data indicating a genuine diastolic pressure gradient between the right ventricle and pulmonary artery.

The main presenting features in our case were related to cardiac lesions rather than the underlying disease, an unusual finding in patients with the carcinoid syndrome.[8] An almost fatal episode of flushing and tissue edema that occurred shortly after cardiac catheterization and angiocardiography may have been coincidental; however, it is likely that cardiac catheterization and angiography were somehow responsible, since these procedures are occasionally followed by fatal complications.[10,11] Cardiac catheterization and angiography should be reserved for patients being considered for cardiac surgery or those in whom there is a question regarding the nature of cardiac disease.[12,13]

Calcium Responses ("Calcium Spikes")

BORYS SURAWICZ, MD, FACC

Lexington, Kentucky

In 1961 Fleckenstein and his co-workers[1] in Freiburg, Germany, reported that adrenaline (5 μg/ml) restores contractility and excitability in amphibian and mammalian myocardium depolarized by potassium (12 to 23 millimoles/liter). These investigators showed that this restitution occurs without change in the resting membrane potential, which ranged from about −30 to −40 mv. The upstroke velocity of action potentials generated by adrenaline in such depolarized tissue was decreased, and the rate of impulse propagation was very slow. However, the overshoot of these action potentials was either normal, or even greater than normal. These unusual findings of Fleckenstein et al. could not be explained by the Hodgkin-Huxley ionic theory governing excitation in the giant squid axon,[2] and in cardiac Purkinje fibers.[3]

In the late 1960's cardiac electrophysiologists made three discoveries that contributed to our understanding of the mechanism of action potentials originating in depolarized myocardium: (1) identification of the inward calcium current, (2) separation of the depolarizing currents into two channels, "rapid" and "slow," and (3) demonstration that the permeability of the calcium current carrying slow channel, is enhanced by adrenaline.

The principal credit for the identification and characterization of the slow inward calcium current in mammalian Purkinje and ventricular myocardial fibers belongs to Reuter.[4–7] He and his co-worker Beeler[5,6] described the kinetics of the current and showed that in a sodium-free solution this current was activated at a threshold potential of about −30 to −40 mv. Reuter also demonstrated that adrenaline causes an increase in calcium influx through the depolarized myocardium.[4]

Role of Calcium in Adrenaline-Induced Depolarization

During the past decade several prominent cardiac electrophysiologists (cited in Ref 8) postulated that the upstroke of the cardiac action potential may be composed of two independent components, a rapid spike and a slower depolarization wave. Strong support of this idea has been provided by the recent voltage-clamp experiments in frog atrial trabeculae.[9] These experiments of Rougier et al.[9] have shown conclusively that the inward depolarizing membrane current flows through two separate "channels": a rapid, pure sodium channel and a slow "mixed" sodium-calcium channel. The rapid channel can be selectively blocked by tetrodotoxin, and the slow channel by manganese and lanthanides.[7,9] Vassort et al.[10] have shown that adrenaline activates the slow channel.

In 1969 Carmeliet and Vereecke[11] repeated and extended the original experiments of the Freiburg group using bovine Purkinje fibers. In their experiments, adrenaline induced propagated action potentials with a slow upstroke in sodium-free solutions and also when the rapid inward sodium current was inactivated by increased extracellular potassium concentration or tetrodotoxin. Such responses did not occur in calcium-free solutions unless calcium was substituted by another divalent ion such as strontium. These experiments confirmed the action of adrenaline on the slow channel and suggested that calcium current was responsible for the slow depolarization. In 1970 Pappano[12] demonstrated a strict mathematical correlation between the amplitude of spikes induced by depolarization and the external calcium concentration, and thereby established the predominant, if not the exclusive role of calcium in the production of adrenaline-dependent depolarizations. These studies justify the term "calcium spikes" for action potentials generated in tissue in which the rapid inward sodium current is inactivated. The effect of catecholamine on the "calcium spikes" is due to beta adrenergic action. Depolarized myocardium is more sensitive to isoproterenol than to adrenaline or noradrenaline, and the response is blocked by propranolol.[12] Caffeine and 3′5′ cyclic adenosine monophosphate (AMP) are also capable of inducing similar responses, but their action is weaker than that of catecholamines.[13,14]

Slow Calcium Responses and Cardiac Arrhythmias

The system of calcium-dependent depolarization appears to be ubiquitous in cardiac muscle since it has been demonstrated in many different types of cardiac fibers in different animal species, including a 9 to 13 day old chick embryo.[14] The unique features of the impulse propagation induced by this type of depolarization have been extensively investigated by Cranefield, Hoffman and Wit.[15–19] These investigators have shown that in canine Purkinje fibers depolarized by potassium, and treated with adrenaline,

the conduction velocity may be as low as 1 percent of normal,[19] and that such slow conduction may be associated with one-way or two-way block, summation, inhibition, reentry and circus movement.[17,18] Cranefield and his colleagues[19] described in detail the differences between the characteristics of the fast and the slow responses and proved conclusively that the pathway for reentry and circus movement of the slow responses may be shorter than 1 cm. They[19] also suggested that acute myocardial ischemia could precipitate such reentrant arrhythmias because in this condition the localized depolarization and local release of catecholamines would create conditions particularly favorable to the appearance of slow responses.

Some of the reentrant arrhythmias produced in dogs with acute ischemia show evidence of very slow conduction.[20,21] This suggests that the depolarizations induced by calcium may, indeed, play an important role in the critical slowing of conduction in the ischemic or otherwise damaged myocardium.

Slow Calcium Response and Spontaneous Myocardial Depolarization

Another interesting problem emerging from the studies of calcium spikes concerns the possibility that slow depolarizations can induce spontaneous propagation of action potentials without the assistance of impulses generated by pacemaker activity in other parts of the heart. Cranefield et al.[19] have pointed out that in most experiments the slow response has been stimulus-dependent. However, spontaneous activity in a depolarized myocardium has been observed. Imanishi[22] showed a rapid succession of calcium-dependent depolarizations in cardiac Purkinje fibers after depolarizations induced by square cathodal current pulses. In our laboratory[23] we have shown that spontaneous depolarizations occurred after the release of voltage-clamp in short canine Purkinje fibers, and that the amplitude of these depolarizations correlated with the strength of the inward current flowing at the time of clamp release. These observations suggest that when the circumstances are appropriate, either single or repetitive depolarizations could arise spontaneously in the depolarized myocardium due to local action of calcium, catecholamines or other depolarizing stimuli. Future studies will undoubtedly focus on this and other aspects of calcium spikes. The new knowledge of these phenomena may bring us significantly closer toward understanding the mechanism of cardiac arrhythmias in patients with acute myocardial infarction and sudden cardiac death.

LETTERS TO THE EDITOR

HEMODYNAMICS IN MYOCARDIAL INFARCTION

In their recent article Russell and co-workers[1] used both pulmonary arterial end-diastolic pressure and left ventricular end-diastolic pressure as indicators of "left ventricular filling pressure." They feel that pulmonary arterial end-diastolic pressure "reliably reflected" left ventricular end-diastolic pressure[1] in acute myocardial infarction, a thesis that needs to be examined critically.[2]

Falicov et al.[3] and Bouchard et al.[4] have shown that pulmonary arterial end-diastolic pressure does not provide a reliable estimate of left ventricular end-diastolic pressure in the presence of chronic left ventricular disease. We have shown previously that pulmonary arterial end-diastolic pressure does not accurately reflect left ventricular end-diastolic pressure after acute myocardial infarction.[5] Since Russell et al. did not present tabulated data for each individual patient, it is difficult to know the precise range of differences between pulmonary arterial end-diastolic pressure and left ventricular end-diastolic pressure in their patients with acute myocardial infarction. Figure 6 of their article showed a comparison of pulmonary arterial end-diastolic pressure and left ventricular end-diastolic pressure and demonstrated that there was a considerable scatter of points. In their patients, the probable difference between pulmonary arterial end-diastolic pressure and left ventricular end-diastolic pressure averaged 2.1 mm Hg with 1 standard deviation of 4.5 mm Hg and a P value of <0.001. In spite of this significant difference between the two pressures, if changes in left ventricular end-diastolic pressure were consistently and accurately reflected in pulmonary arterial end-diastolic pressure, then monitoring of the latter could be useful as an indicator of ventricular performance. Unfortunately, in many patients this does not occur. For example, Figure 6 from Russell's data[1] shows that in one patient left ventricular end-diastolic pressure and pulmonary arterial end-diastolic pressure were the same at 20 mm Hg, but at another time, when left ventricular end-diastolic pressure had increased to 30 mm Hg, pulmonary arterial end-diastolic pressure was unchanged at 20 mm Hg. In another patient both pressures were 18 mm Hg and when left ventricular end-diastolic pressure increased to 29 mm Hg, pulmonary arterial end-diastolic pressure fell to 16 mm Hg. Further, it has also been shown previously that various maneuvers may result in changes in the indirect estimates of left ventricular end-diastolic pressure (such as pulmonary arterial end-diastolic pressure) that are different not only in magnitude but also in direction from the changes seen in left ventricular end-diastolic pressure.[2,4]

The use to which the various measured pressures are to be put is clearly important. As we have pointed out previously,[2,5] if left ventricular filling pressures are monitored in patients with acute myocardial infarction, the following data are important: (1) left ventricular end-diastolic pressure to assess the performance characteristics of the left ventricle, and (2) mean left atrial pressure or mean pulmonary arterial wedge pressure or left ventricular diastolic pressure, pre *a* wave, to assess the pulmonary venous pressure and, thus, the risk to the patient that pulmonary edema will develop. Pulmonary arterial end-diastolic pressure gives a good indication of pulmonary venous pressure, but after myocardial infarction pulmonary arterial end-diastolic pressure may not be the same as mean pulmonary arterial wedge pressure because of some increase of pulmonary vascular resistance in many patients.[5] The difference between the two pressures may create a problem because it is easier to monitor pulmonary arterial end-diastolic pressure than mean pulmonary arterial wedge pressure over a period of several days. A Swan-Ganz catheter can be placed in the pulmonary artery and pulmonary arterial end-diastolic pressure and mean pulmonary arterial wedge pressure determined. If there is a discrepancy between the two pressures, the magnitude of the difference can be taken into account during monitoring of pulmonary arterial end-diastolic pressure.

In conclusion, in normal subjects the indirect estimates of left ventricular end-diastolic pressure (for example, pulmonary arterial end-diastolic pressure and mean pulmonary arterial pressure) are usually the same as left ventricular end-diastolic pressure, and "left ventricular filling pressure" may be used as a convenient term to refer to all of these indexes. However, in patients with left ventricular dysfunction the indirect estimates of left ventricular end-diastolic pressure are often not the same as left ventricular end-diastolic pressure and, further, may not accurately reflect changes in this pressure. Therefore, it would seem inappropriate to use the general term "left ventricular filling pressure" in patients with left ventricular dysfunction. It would be preferable to refer to the specific index measured instead of using "filling pressure" to cover all indexes.[2] Such a practice would be more accurate and would allow maximal utilization of data from studies performed by various investigators.

REPLY

We appreciate the interest expressed by Dr. Rahimtoola in our recent article[1] and the opportunity to clarify and amplify our position concerning the interpretation and clinical usefulness of pulmonary arterial end-diastolic pressure in acute myocardial infarction. We agree that each investigator and clinician should specify the variable measured in discussion of his results.[2] However, once clearly specified, it seems defensible and reasonable to employ some term such as left ventricular filling pressure[3] in reference to diastolic pressure events in the left ventricle to remind the clinician constantly that the Frank-Starling principle can be employed to manage acutely ill patients, including those with acute myocardial infarction.

We also agree that it is important to consider how the measured pressures are to be used. The clinician has become interested in measurement of left ventricular end-diastolic pressure, or a reasonably reliable reflection of it, particularly in the acutely ill patient, because (1) it provides information concerning the function of the left ventricle; (2) he may wish to alter it acutely, thus altering preload; and (3) it may provide information concerning the risk of pulmonary edema in the patient. As Rahimtoola indicates, there is little disagreement that, in the absence of increased pulmonary vascular resistance, pulmonary arterial end-diastolic pressure gives a good indication of pulmonary venous pressure and, thus, of the risk that pulmonary edema will develop.[4,5]

Debate persists concerning the validity of pulmonary arterial end-diastolic pressure as an indication of left ventricular end-diastolic pressure. In patients with chronic left ventricular disease the left ventricular end-diastolic pressure is greater than mean left atrial pressure as a result of atrial systole; in subjects with normal cardiovascular systems the left ventricular end-diastolic pressure and the mean left atrial pressure are approximately equal.[6] Knowledge of left ventricular end-diastolic pressure, or a reasonable reflection of it, provides important information regarding the performance characteristics of the left ventricle with respect to its preload or the forces within the wall of the ventricle at end-diastole. Although performance of the left ventricle is determined by its preload, its afterload, heart rate and intrinsic contractility, estimation of left ventricular preload is the focus of this discussion. Whereas preload is determined by left ventricular end-diastolic pressure, left ventricular end-diastolic volume (and the previous end-systolic volume), wall thickness and left ventricular geometry, the left ventricular end-diastolic pressure provides an acceptable estimate of preload. Control of left ventricular end-diastolic pressure allows a certain degree of regulation of left ventricular performance by the Starling mechanism.[7] Thus, left ventricular end-diastolic pressure, or a reasonable reflection of this measurement, is important to the clinician, particularly in the management of the acutely ill patient.

Although direct measurement of left ventricular pressure may be performed in patients with myocardial infarction,[8,9] hemodynamic monitoring for serial evaluation of the patient's course is hazardous because of arrhythmias and possible embolic phenomena.[10] Furthermore, Parmley et al.[11] found that measurement of left ventricular pressure provided little more information of clinical value than that obtained with the pulmonary arterial balloon catheter and measurement of cardiac output. Because of these considerations the search for a suitable substitute for left ventricular end-diastolic pressure has engendered much meritorious investigation.[4,5,12–19] Clearly, central venous pressure or mean right atrial pressure does not provide a meaningful substitute.[1,13,20,21] Although inflation of the balloon of the Swan-Ganz catheter gives a pulmonary wedge pressure that closely approximates mean left atrial pressure or a pre *a* wave left ventricular diastolic pressure, frequent inflation of the balloon leads to further floating of the catheter and the risk of pulmonary infarction. The balloon may inadvertently be left inflated or improperly deflated and the hazard of pulmonary infarction thus exists.

Pulmonary arterial end-diastolic pressure is frequently not precisely equal to left ventricular end-diastolic pressure in patients with acute myocardial infarction.[1,17] Nor are the two precisely equal in patients with myocardial disease or other forms of chronic left ventricular dysfunction,[4,14] particularly in patients with increased pulmonary vascular resistance,[4] or at heart rates faster than 125 beats/min or in the atrial fibrillation during short cycle lengths.[14] However, in our experience, pulmonary arterial end-diastolic pressure should not be measured "at the lowest point of its tracing" as suggested previously by Rahimtoola and associates.[17] The catheter with its tip in the pulmonary artery also lies partly in the right ventricle. The contraction of this chamber must frequently strike the catheter, producing motion artefact with resultant undershoot and doubtless falsification of the pressure as lower than physiologically present, if measured at the lowest point. We have observed commercial analog pressure read-out devices perform in this physiologically erroneous manner when attempting to read pulmonary arterial end-diastolic pressure. A more appropriate method, we believe, is to read the pressure on the plateau before the rise in the level of pulmonary arterial systolic pressure. One can judge this segment of pressure by visually averaging the fluctuations at this period on the pressure curve. Lest this be thought to be somewhat "individual," we have taught numerous physicians, nurses and technicians to read this pressure and a digital computer program has been written that seeks this plateau by finding the segment with least rapid pressure changes in this period of the cardiac cycle.

It remains to consider the use of pulmonary arterial pressure to assess the performance characteristics of the left ventricle. Rutherford et al.[16] demonstrated the separation of patients after myocardial infarction into those with and without a complicated course using mean pulmonary arterial pressure. Values for stroke volume index and pulmonary arterial oxygen saturation supported this classification. Rapaport and Scheinman[13] pointed out the value of pulmonary arterial end-diastolic pressure in management of the critically ill patient with shock or congestive heart failure. Rotman et al.[18] noted correlation of pulmonary arterial end-diastolic pressure with clinical classification, site of infarction, presence or absence of a third heart sound and rales and with hospital mortality. We have evaluated left ventricular performance on the basis of function curves relating cardiac index, stroke volume index or stroke work index to pulmonary arterial end-diastolic pressure as the latter is altered by rapid infusion of low molecular weight dextran with blood volume expansion.[22] We found that the ventricle does indeed follow a ventricular function curve using pulmonary arterial end-diastolic pressure as a reflection of left ventricular end-diastolic pressure. We have also found that the cardiac output after acute myocardial infarction can be increased and that the ventricle reaches a peak stroke index or cardiac index in the range of a pulmonary arterial end-diastolic pressure of 20 to 24 mm Hg although there is individual patient variation. The performance of the ventricle after acute myocardial infarction improves spontaneously in the first 2 or 3 days in the absence of any specific therapy as judged by these ventricular function curves.[22] Thus, the performance of the left ventricle can be serially monitored from pulmonary arterial end-diastolic pressure. However, if in the presence of left ventricular pump failure with cardiogenic shock or of pulmonary parenchymal disease with increased pulmonary vascular resistance, there is reason to suspect discrepancy between pulmonary arterial end-diastolic pressure and left ventricular end-diastolic pressure or pulmonary capillary wedge pressure, one of these latter two pressures should be measured initially and the pulmonary arterial end-diastolic pressure calibrated for serial monitoring.

Let us summarize our thinking on the clinical usefulness

of pulmonary arterial end-diastolic pressure as a correlate and substitute for left ventricular end-diastolic pressure: (1) It may be hazardous to monitor serially left ventricular end-diastolic pressure or pulmonary capillary wedge pressure. (2) Pulmonary arterial end-diastolic pressure and left ventricular end-diastolic pressure are similar in the absence of mitral valve disease, pulmonary parenchymal disease of moderate or marked severity, hypoxia, acidosis or alkalosis (which might alter pulmonary vascular tone) and heart rates exceeding 125 beats/min. (3) The method of measuring pulmonary arterial end-diastolic pressure is important. (4) The use of pulmonary arterial end-diastolic pressure is to provide a means to monitor the raising or lowering of left ventricular pre *a* wave and end-diastolic pressure without producing pulmonary edema. Experience suggests that this is feasible in the majority of patients with acute myocardial infarction even though a discrepancy may exist between pulmonary arterial end-diastolic pressure and left ventricular end-diastolic pressure. Furthermore, there is prognostic value in the pulmonary arterial end-diastolic pressure. (5) The term left ventricular filling pressure derives from earlier experimental studies relating mean left atrial pressure to left ventricular end-diastolic pressure. The term has come into common usage even though the implication that pulmonary arterial end-diastolic pressure, left ventricular end-diastolic pressure and left ventricular filling pressure are freely interchangeable is misleading. Nevertheless, the usage seems likely to continue.

MEDICALLY UNCONTROLLABLE RECURRENT VENTRICULAR TACHYARRHYTHMIA IN ASSOCIATION WITH VENTRICULAR ANEURYSM

Clark and Russell[1] recently presented a case of recurrent ventricular tachycardia associated with ventricular aneurysm, controlled by medical treatment. Attention is drawn to a paper of Lull et al.,[2] in which surgical treatment was indicated in one case of ventricular tachycardia associated with myocardial sarcoidosis. Wasserman and Yules[3] indicated an association between intractable ventricular tachycardia and ventricular aneurysm, although some cases were reported previously.

In 1959, Couch[4] reported the first case of refractory ventricular tachycardia successfully treated by surgery with resection of a postinfarction ventricular aneurysm. Similar cases have since been reported.[5–8] Progressive congestive heart failure caused by tachyarrhythmia was considered by Lenegre et al.[9] the primary indication for surgery.

As a contribution to the subject, we describe three patients who underwent surgery for ventricular tachyarrhythmia associated with ventricular aneurysm not controlled by medical treatment.

Case 1: A 59 year old man with a history of two previous myocardial infarctions in 1965 and January 1971; the last was located on the posterior wall and produced mitral insufficiency. He was admitted into the coronary unit in September 1971, when his course was complicated by sinus tachycardia, left anterior hemiblock, right bundle branch block, atrioventricular (A–V) junctional rhythm at times, and paroxysmal ventricular tachycardia without signs of pulmonary congestion at rest.

Vigorous treatment with antiarrhythmic drugs proved a failure. Ten days later coronary arteriography and angiocardiography showed a left ventricular aneurysm of the posterior wall involving also the apex of the left ventricle, mitral insufficiency, enlarged left atrium without thrombus and severe coronary disease. Twenty-one days after admission, external plication of the aneurysm and valvuloplasty of the mitral valve were performed in addition to endarterectomy of the right coronary artery and right aortocoronary artery bypass. The insertion of the posterior papillary muscle of the mitral valve was found in the center of the aneurysmal sac, thus partially explaining the mitral insufficiency. The patient was discharged 11 days after operation and during the past 18 months has had no recurrence of ventricular tachycardia. A recent examination, June 1973, showed that he has sinus rhythm and is performing his habitual duties normally.

Case 2: A 59 year old man had an anteroseptal myocardial infarction in March 1971. He was admitted several times into the hospital with recurrent tachyarrhythmia without chest pain, dypsnea or heart failure at rest. In spite of vigorous antiarrhythmic drug treatment, only direct current electrical shock reverted the rhythm to normal tempo-

rarily. On January 18, 1972, angiocardiography and coronary arteriography revealed an anteroseptal aneurysm extending to the apex of the left ventricle and severe atherosclerosis of the three coronary vessels. Thirty-seven days after admission, resection of the left ventricular aneurysm, endarterectomy and saphenous vein bypass graft of the right coronary artery were performed. There was no recurrence of tachyarrhythmia for 1 year after surgery. Then the patient experienced two episodes of supraventricular tachycardia that were rapidly controlled by direct current electrical countershock. Since then there has been no recurrence of arrhythmia and the patient is leading a normal life.

Case 3: A 56 year old man with no previous history of angina was admitted to the coronary care unit on December 9, 1972 because of anteroseptal and posterior myocardial infarction. On admission a holosystolic precordial impulse was palpable. For 10 days the patient had isolated ventricular extrasystoles controlled by antiarrhythmic drugs. On the 26th day he manifested bigeminy followed by ventricular fibrillation, from which he was resuscitated by direct current electrical countershock. However, ventricular extrasystoles persisted, and at times bigeminy and on four occasions ventricular tachycardia occurred. Coronary arteriography and angiocardiography performed 32 days after hospital admission revealed a giant anterolateral aneurysm that covered more than 40 percent of the left ventriculogram, and severe diffuse coronary disease. In spite of vigorous medical treatment the patient had bouts of ventricular tachycardia. He was operated on as an emergency case, because of uncontrolled tachycardia, 39 days after myocardial infarction, and aneurysmectomy was performed. The patient was discharged on the 14th postoperative day with normal sinus rhythm. A recent examination in June 1973 indicated that he is leading a normal life.

In summary, medically uncontrollable tachyarrhythmia forced us to carry out surgical treatment in these three patients. In the first case plication of a posterior wall aneurysm, mitral valvuloplasty and right aortocoronary vein bypass combined with endarterectomy abolished the ventricular arrhythmia for 18 months. In Case 2, aneurysmectomy and right coronary bypass associated with right endarterectomy have prevented ventricular tachyarrhythmia for more than a year. Two episodes of supraventricular tachycardia were easily controlled by electrical shock, and there has been no recurrence in the last 6 months of observation. In Case 3 aneurysmectomy alone was performed. All three patients had advanced ischemic heart disease with diffuse coronary atherosclerosis. This diagnosis was confirmed by the finding that, in two patients, revascularization of the right coronary artery was possible only with combined endarterectomy.

Surgery was of definite benefit in all three cases after failure of medical treatment. We believe that medical therapy including cardioversion, cardiac pacing and antiarrhythmic drugs are useful to reverse the arrhythmic episodes but, in the presence of severe repetitive tachyarrythmia, surgery is indicated to obtain a permanent result.

BOOK REVIEWS

CHANGING CONCEPTS IN CARDIOVASCULAR DISEASE edited by Henry I. Russek and Burton L. Zohman. Baltimore, Williams & Wilkins, 1972, 469 pages, $23.75

This volume contains the edited proceedings of the 1970 American College of Cardiology Saint Barnabas Symposium on New Frontiers in Cardiovascular Disease. The diverse scope of the book reflects the contributions of 56 authors on topics ranging from the ultrastructure of the myocardium, coronary artery disease, heart failure, cardiac arrhythmias, pulmonary heart disease, mechanical assistance and surgical excision, hypertension, exercise and periontogenic disease to human transplantation. Their discussions provide a summary of work in progress as well as classic work in various fields.

The major problems in this text are the lack of continuity between chapters and topics and the disproportionate amount of space alloted to certain material and the restriction of other subjects of equal importance (management of dissecting aneurysm of the aorta) to two pages. Many chapters are devoted to exercise and physical fitness, and there is a long, well illustrated, surgically oriented chapter on autologous tissue repair in mitral and aortic valvular disease (37 pages); only 5 pages are devoted to direct myocardial revascularization—a timely topic. Some chapters are especially well referenced (myocardial potassium balance, recent advances in the understanding of congestive heart failure, diagnosis and treatment of cardiomyopathy and physiologic basis of antianginal therapy), others not at all. Most are well written, but some provide inadequate discussion and analysis of a given subject matter and do not review controversial aspects.

The title of the book may be misleading to some, since the scope is of limited interest. Recent pharmacologic, electrophysiologic and surgical advances are omitted as are the newer noninvasive techniques, and the book provides only an incomplete review of some changing concepts in cardiovascular disease.

CENTRAL HEMODYNAMICS AND GAS EXCHANGE (WITH EMPHASIS ON THE MEASUREMENT OF PULMONARY EXTRAVASCULAR WATER), edited by C. Giuntini, MD. Torino, Italy, Minerva Medica, 1971, 475 pages, $22.25

Although this text is a compilation of individual papers presented at a symposium on pulmonary water and water compartments, it is by no means a disjointed set of unrelated manuscripts, as is so often the case with the published records of scientific symposia. On the contrary, this book is a comprehensive overview of the present status of the theoretical and practical basis for the measurement of lung extravascular water, of the physiology of the pulmonary water compartments, that is, their osmotic and interstitial pressure and their extent, and the use of measurements in both man and animals during health and disease.

In the first section of the text, Zierler, Chinard et al. and Goreski et al. present theoretical reinforcement of present measurement techniques: The interested reader approaching this problem for the first time can quickly become acquainted with the development of these relatively sophisticated indicator-dilution techniques. Although much is a recapitulation of developments in this area over the past 20 years, new hypotheses, such as that of Zierler and Permutt on the relation between pulmonary blood flow and pulmonary extravascular water, are developed. The second section of the text tackles the difficult problems involving the physiology of the pulmonary water spaces and contains contributions by both West and Guyton. The latter's paper is an updated version of work defining interstitial pressures in tissue due to the presence of both solids and liquids and presents clearly what has always been a most difficult subject. The final section of the text features 10 contributions reporting techniques to measure lung water under a variety of circumstances in man. Thus, the effects of various factors on the pulmonary water compartments: (exercise in cardiac patients, acute hypoxia, myocardial infarction, early pulmonary edema, pulmonary embolism and the special pulmonary edema of high altitude) are all reported. It is apparent that much can be learned about the pathogenesis of various forms of pulmonary edema from meticulous measurements of the distribution of water throughout the lung by these techniques.

This volume ends appropriately with a proposal by Staub for a formalized nomenclature for the pulmonary "spaces" similar to the systems of symbols adapted by the respiratory and renal physiologists to make certain that investigators understand each other. The pertinence of such a system is underscored by the recent development of this hitherto specialized field of investigation into a much used approach in the study of human disease.

AUDIOVISUAL SEMINARS IN PEDIATRICS. PEDIATRIC CARDIOLOGY, first edition, by Roland Schmidt, MD and George H. Khoury, MD. Philadelphia, WB Saunders, 1973, 83 pages, $75.00

The Pediatric Cardiology supplement of Audiovisual Seminars in Pediatrics is an innovative, although not particularly valuable, teaching aid. The "book" or unit consists of two taped cassettes (one half hour of recorded material on each side), four film strips corresponding to and coordinated with the tapes, and an accompanying 83 page pamphlet, much like an unabridged libretto, that reproduces the taped scenario word for word. The two subjects of discussion, cardiac examination of the child and rheumatic fever in children, are each 1 hour long when played; however, the material in the accompanying brochure can be read easily in less than 30 minutes. Included in the taped material are clinical examples of pathologic and innocent murmurs, but their reproduction on my own solid state cassette recorder left something to be desired. In all fairness, however, the authors recommend more sophisticated audio equipment for optimal results in playback. The user of this unit must also have access to a special film strip projector for the visual component of the learning process.

Because of the inherent time limitation in the method of presentation, the material is somewhat fragmentary and superficial. From an educational standpoint the text relates more to the requirements of a medical student rather than to the expanding horizons of the cardiologist. In general, I would say that the cost (in time and money) to benefit ratio of this pedagogic technique weighs heavily in favor of the former. Furthermore, without some drastic improvements, audiovisual seminars could hardly be expected to serve as a substitute for the patient or a standard textbook.

Norms for Use in the Peer Review of Selected In-Hospital Cardiovascular Diagnoses

Developed by The American College of Cardiology
Bethesda, Maryland, February 1974*

FOREWORD

The ACC PSRO Sub-committee on Norms (defined as a numerical or statistical measure of usual observed performance) functioned within the following framework set forth by the ACC PSRO Committee:

"Realizing the importance of quality of patient care, we propose that the American College of Cardiology develop indices for use in reviewing the quality of cardiovascular practice. Furthermore, we propose that these indices be developed with regional input and that the indices be made available to all legitimate groups engaged in furthering the quality of patient care.

We also recognize that these American College of Cardiology indices may require regional modification and that certainly they will require review at intervals no longer than one year.

The development of these indices should not be interpreted as an indication of the American College of Cardiology's support of any program that would result in a constraint of the practice of cardiology or restriction of innovation."

The Sub-committee addressed itself to a hospital population and within this population identified and developed norms for diagnosis which comprise 75 percent of cardiovascular admissions. The list of special supporting procedures may appear all inclusive. This seemed proper because complications frequently modify the initially projected length of hospital stay, diagnostic and therapeutic approach. The norms as presented will be subject to periodic review.

Finally, the Sub-committee did not concern itself with criteria (defined as predetermined elements against which aspects of the quality of a medical service may be compared) nor with standards (defined as professionally developed expression of the range of acceptable variation from a norm or criteria).

---

*Members of The Ad Hoc Committee appointed by College President H. J. C. Swan for the Development of Cardiovascular Norms are: Charles Fisch, MD, Chairman; Maxwell G. Berry, MD: Louis Gillespie, Jr., MD; R. Joe Noble, MD; Brendan Phibbs, MD; Arthur Selzer, MD; and Sylvan L. Weinberg, MD.

DIAGNOSIS:
ARTERIOSCLEROTIC HEART DISEASE

I. *Indications for admission*
- A. Diagnostic: To establish new or additional diagnoses
- B. Therapeutic: Initial treatment—unresponsive to outpatient regimens
- C. Complications: New symptoms or findings
  1. Unstable angina
  2. Myocardial infarction (See under myocardial infarction)
  3. Congestive failure (See under congestive failure)
  4. Arrhythmias
  5. Involvement of other organ systems

II. *Criteria for diagnosis*
- A. History
  1. No symptoms may be present
  2. Symptoms
     - a. Pain (chest, either arm, neck, throat, upper abdomen); pain equivalents (pressure, burning, tingling, nausea)
     - b. Shortness of breath
     - c. Weakness
     - d. Cough
     - e. Swelling (feet, ankles, legs)
     - f. Cyanosis (bluish discoloration of lips or nailbeds)
     - g. Palpitation, syncope
     - h. Syncope and/or seizures
- B. Physical findings
  1. Enlargement of heart
  2. Fluid retention
     - a. Congestion in lungs
     - b. Distention of neck vein
     - c. Engorgement of liver or spleen
     - d. Edema of lower extremities
     - e. Ascites
     - f. Pleural effusion
     - g. Pericardial effusion
  3. Auscultatory abnormalities
     - a. Heart murmurs
     - b. Gallop sounds (S_2–S_3)
     - c. Pericardial friction rub
  4. Abnormalities of heart rate, rhythm and blood pressure
  5. Heart may be normal on physical examination
  6. Pulsus alternans
- C. Laboratory tests
  1. Usual
     - a. Chest X-ray
     - b. Electrocardiogram
     - c. Complete blood count
     - d. Urinalysis
     - e. Sedimentation rate
     - f. Blood urea nitrogen
     - g. Creatinine
     - h. Serum electrolytes
     - i. Blood sugar
     - j. Enzymes
  2. Occasional
     - a. Blood gases
     - b. Lipids
     - c. Prothrombin time
     - d. Uric acid
     - e. Appropriate as indicated to define further cardiovascular system or other organ systems
- D. Special diagnostic procedures
  1. Cardiac fluoroscopy
  2. Central venous pressure
  3. Vectorcardiogram
  4. Phonocardiogram
  5. Apex cardiogram
  6. Coronary arteriogram
  7. Cardiac catheterization
  8. Echocardiogram
  9. Stress testing
  10. Pericardiocentesis
  11. Pulmonary arteriogram
  12. Lung scan

III. *Basic medical management*
- A. Special care unit
  1. Coronary—intensive care
  2. Respiratory care
  3. Convalescent monitoring unit
- B. Therapy, medical
  1. Usual
     - a. Drug therapy
     - b. Intravenous fluids
     - c. Oxygen therapy
  2. Occasional
     - a. Pacemaker
     - b. Cardioversion
     - c. Defibrillation
- C. Therapy, surgical
  1. Pacemakers
  2. Heart surgery
  3. Intraaortic balloon assist device
  4. Embolectomy
  5. Cardiac transplantation

IV. *New or additional diagnosis (e.g., complications)*
- A. Renal failure
- B. Hepatic failure
- C. Pneumonia
- D. Systemic emboli
- E. Pulmonary emboli
- F. Endocarditis
- G. Stroke
- H. Diabetic acidosis
- I. Sepsis
- J. Shock
- K. Congestive heart failure
- L. Pericarditis
- M. Cardiac rupture
- N. Arrhythmias
- O. Myocardial rupture
- P. Myocardial aneurysm
- Q. Papillary muscle dysfunction
- R. Valvular involvement
- S. Psychosis
- T. Thrombophlebitis

V. *Consultations*
- A. Internal medicine/cardiology
- B. As required by #IV above
- C. Surgical

VI. *Length of hospital stay (with applicable modifiers)*
Range 0 to indefinite as may be modified by #IV above

VII. *Factors modifying standard care*
- A. Renal failure
- B. Hepatic failure
- C. Pneumonia
- D. Systemic emboli
- E. Pulmonary emboli
- F. Endocarditis
- G. Stroke
- H. Diabetic acidosis
- I. Sepsis
- J. Shock
- K. Congestive heart failure
- L. Pericarditis
- M. Cardiac rupture
- N. Arrhythmias
- O. Myocardial rupture
- P. Myocardial aneurysm
- Q. Papillary muscle dysfunction
- R. Valvular involvement
- S. Psychosis
- T. Thrombophlebitis

DIAGNOSIS:
MYOCARDIAL INFARCTION, UNCOMPLICATED

I. *Indications for admission*
- A. No symptoms may be present
- B. Symptoms
  1. Pain (chest, either arm, neck, throat, upper abdomen); pain equivalents (pressure, burning, tingling, nausea)
  2. Shortness of breath
  3. Weakness

II. *Criteria for diagnosis*
- A. History
  1. No symptoms may be present
  2. Symptoms
     a. Pain (chest, arm, neck, throat, upper abdomen); pain equivalents (pressure, burning, tingling, nausea)
     b. Shortness of breath
     c. Weakness
     d. Cough
     e. Swelling (feet, ankles, legs)
     f. Cyanosis
     g. Palpitations, syncope
     h. Syncope and/or seizures
- B. *Physical findings*
  1. Enlargement of heart
  2. Fluid retention
     a. Congestion in lungs
     b. Distention of neck vein
     c. Engorgement of liver or spleen
     d. Edema of lower extremities
     e. Ascites
     f. Pleural effusion
     g. Pericardial effusion
  3. Auscultatory abnormalities
     a. Heart murmurs
     b. Gallop sounds (S_2–S_3)
     c. Pericardial friction rub
  4. Abnormalities of heart rate, rhythm and blood pressure
  5. Heart may be normal on physical examination
  6. Pulsus alternans

  2. Usual additions
     a. Drug therapy
     b. Intravenous fluids
     c. Oxygen therapy
  3. Occasional additions
     a. Pacemaker
     b. Cardioversion
     c. Defibrillation
- C. Therapy, surgical
  None

IV. *New or additional diagnosis (e.g., complications)*
- A. Renal failure
- B. Hepatic failure

C. Pneumonia
D. Systemic emboli
E. Pulmonary emboli
F. Endocarditis
G. Stroke
H. Diabetic acidosis
I. Sepsis
J. Shock
K. Congestive heart failure
L. Pericarditis
M. Cardiac rupture
N. Arrhythmias
O. Myocardial rupture
P. Myocardial aneurysm
Q. Papillary muscle dysfunction
R. Valvular involvement
S. Psychosis
T. Thrombophlebitis

V. *Consultations*
None may be required

VI. *Length of hospital stay (with applicable modifiers)*
A. Coronary care unit or other specialized units: range 0–7 days
B. Intermediate care unit or monitoring facility when available, for duration of hospital stay: range 14–17 days
C. Total hospital stay: range 14–24 days

VII. *Factors modifying standard care*
A. Renal failure
B. Hepatic failure
C. Pneumonia
D. Systemic emboli
E. Pulmonary emboli
F. Endocarditis
G. Stroke
H. Diabetic acidosis
I. Sepsis
J. Shock
K. Congestive heart failure
L. Pericarditis
M. Cardiac rupture
N. Arrhythmias
O. Myocardial rupture
P. Myocardial aneurysm
Q. Papillary muscle dysfunction
R. Valvular involvement
S. Psychosis
T. Thrombophlebitis

DIAGNOSIS:
SYSTEMIC ARTERIAL HYPERTENSION (BASIC)

I. *Indications for admission*
A. Sustained elevated diastolic blood pressure with clinical suspicion of secondary cause of hypertension
B. Failure to respond to antihypertensive therapy

II. *Criteria for diagnosis*
A. History
Sustained elevation of diastolic blood pressure
B. Physical findings
Sustained elevation of diastolic blood pressure; no other findings necessary
C. Laboratory tests
1. Usual
a. Chest X-ray
b. Complete blood count
c. Urinalysis
d. Blood urea nitrogen
e. Creatinine
f. Serum electrolytes
g. Blood sugar
h. Electrocardiogram
2. Occasional
a. Urine culture
b. Urinary VMA or catecholamines
c. Plasma or urinary steroids
d. Creatinine clearance
e. Urinary aldosterone
f. Lipoprotein electrophoresis
g. Serum triglycerides
h. Glucose tolerance test
D. Special diagnostic procedures
1. Excretory urogram
2. Renal arteriogram
3. Renal vein and/or peripheral venous renin assays
4. Cystoscopy with retrograde pyelography and/or separate renal function studies

III. *Basic medical management*
A. Special care unit
None needed
B. Therapy, medical
Drug therapy
C. Therapy, surgical
Renal, adrenal or vascular surgery

IV. *New or additional diagnosis (e.g., complications)*
A. Congestive heart failure
B. Renal failure (azotemia)
C. Hypertensive encephalopathy
D. Subarachnoid or intracerebral hemorrhage
E. Difficulty in regulating antihypertensive drugs
F. Surgery
G. Involvement of other organ systems
H. Epistaxis

V. *Consultations*
A. Internal medicine/cardiology
B. Urology
C. Surgery
D. As required by # IV

VI. *Length of hospital stay (with applicable modifiers)*
Range 1–28 days

VII. *Factors modifying standard care*
A. Congestive heart failure
B. Renal failure (azotemia)
C. Hypertensive encephalopathy
D. Subarachnoid or intracerebral hemorrhage
E. Difficulty in regulating antihypertensive drugs
F. Surgery
G. Involvement of other organ systems
H. Epistaxis

DIAGNOSIS:
SYSTEMIC ARTERIAL HYPERTENSION
(ACUTE ONSET IN ADULT)

I. *Indications for admission*
  A. Sustained elevated diastolic blood pressure
  B. Clinical suspicion of secondary cause of hypertension
II. *Criteria for diagnosis*
  A. History
    Sustained elevation of diastolic blood pressure
  B. Physical findings
    1. Sustained elevation of diastolic blood pressure
    2. no other findings necessary
  C. Laboratory tests
    1. Usual
      a. Chest X-ray film
      b. Complete blood count
      c. Urinalysis
      d. Blood urea nitrogen
      e. Creatinine
      f. Serum electrolytes
      g. Blood sugar
      h. Electrocardiogram
      i. Uric acid
      j. Serum cholesterol
    2. Occasional
      a. Urine culture
      b. Urinary VMA or catecholamines
      c. Plasma or urinary steroids
      d. Creatinine clearance
      e. Urinary aldosterone
      f. Lipoprotein electrophoresis
      g. Serum triglycerides
      h. Glucose tolerance test
  D. Special diagnostic procedures
    1. Excretory urogram
    2. Renal arteriogram
    3. Renal vein and/or peripheral venous renin assays
    4. Cystoscopy with retrograde pyelography and/or separate renal function studies
III. *Basic medical management*
  A. Special care unit
    1. Possible intensive care unit—i.e., acute congestive heart failure
    2. Possible renal dialysis unit—i.e., acute or chronic renal failure requiring dialysis
  B. Therapy, medical
    1. Usual
      Drug therapy
    2. Occasional
      Special dietary restrictions
  C. Surgical
    Renal, adrenal or vascular surgery
IV. *New or additional diagnosis (e.g., complications)*
  A. Congestive heart failure
  B. Renal failure (azotemia)
  C. Hypertensive encephalopathy
  D. Subarachnoid or intracerebral hemorrhage
  E. Difficulty in regulating antihypertensive drugs
  F. Surgery
  G. Involvement of other organ systems
  H. Epistaxis
V. *Consultations*
  A. Internal medicine/cardiology
  B. Urology
  C. Surgery
  D. Renal
  E. As required by #IV
VI. *Length of hospital stay (with applicable modifiers)*
  Range 1–28 days
VII. *Factors modifying standard care*
  A. Congestive heart failure
  B. Renal failure (azotemia)
  C. Hypertensive encephalopathy
  D. Subarachnoid or intracerebral hemorrhage
  E. Difficulty in regulating antihypertensive drugs
  F. Surgery
  G. Involvement of other organ systems
  H. Epistaxis

DIAGNOSIS:
SYSTEMIC ARTERIAL HYPERTENSION
WITH ENCEPHALOPATHY

I. *Indications for admission*
  A. Elevated diastolic blood pressure with neurologic or sensorium abnormalities
II. *Criteria for diagnosis*
  A. History
    1. Elevation of diastolic blood pressure
    2. Possible abnormality of sensorium
  B. Physical findings
    1. Elevation of diastolic blood pressure
    2. Possible neurologic abnormalities
    3. Fundoscopy noted: positive or negative findings
  C. Laboratory tests
    1. Usual
      a. Chest X-ray film
      b. Complete blood count
      c. Urinalysis
      d. Blood urea nitrogen
      e. Creatinine
      f. Serum electrolytes
      g. Blood sugar
      h. Electrocardiogram
      i. Uric acid
      j. Serum cholesterol
    2. Occasional
      a. Urine culture
      b. Urinary VMA or catecholamines
      c. Plasma or urinary steroids
      d. Creatinine clearance
      e. Urinary aldosterone
      f. Lipoprotein electrophoresis
      g. Serum triglycerides
      h. Glucose tolerance test
      i. Spinal fluid examination
  D. Special diagnostic procedures
    1. Usual

a. Excretory urogram
b. Renal arteriogram
c. Renal vein and/or peripheral venous renin assays
d. Cystoscopy with retrograde pyelography and/or separate renal function studies

2. Occasional
a. Electroencephalogram
b. Brain scan
c. Cerebral arteriography

III. *Basic medical management*
A. Special care unit
Possible intensive care unit
B. Therapy, medical
1. Usual
Drug therapy
2. Occasional
Special dietary restrictions
C. Therapy, surgical
Renal, adrenal or vascular surgery

IV. *New or additional diagnosis (e.g., complications)*
A. Congestive heart failure
B. Renal failure (azotemia)
C. Hypertensive encephalopathy
D. Subarachnoid or intracerebral hemorrhage
E. Difficulty in regulating antihypertensive drugs
F. Surgery
G. Involvement of other organ systems
H. Epistaxis

V. *Consultations*
A. Internal medicine/cardiology
B. Surgery
C. Urology
D. As required by #IV

VI. *Length of hospital stay (with applicable modifiers)*
Range 5–20 days

VII. *Factors modifying standard care*
A. Congestive heart failure
B. Renal failure (azotemia)
C. Hypertensive encephalopathy
D. Subarachnoid or intracerebral hemorrhage
E. Difficulty in regulating antihypertensive drugs
F. Surgery
G. Involvement of other organ systems
H. Epistaxis

DIAGNOSIS: CONGESTIVE HEART FAILURE

I. *Indications for admission*
A. Diagnostic admission, i.e., to establish etiology, functional significance of lesion, anatomical or physiological derangement
B. New diagnosis, to establish response to therapy
C. Unresponsive to outpatient management
D. Complications

II. *Criteria for diagnosis*
A. History
1. May be asymptomatic
2. Usually: dyspnea, fatigability, effort intolerance, edema

B. Physical findings
1. May be normal
2. S_3 or S_4 heart sounds
3. Pulmonary rales
4. Cardiac murmurs
5. Abdominal organomegaly
6. Edema
7. Venous hypertension

C. Laboratory tests
1. Usual
a. Chest X-ray film
b. Electrocardiogram
c. Blood urea nitrogen or creatinine
d. Hemoglobin or hematocrit
e. Urinalysis
f. Serum electrolytes
g. Uric acid
2. Occasional
a. Cardiac enzymes
b. Creatinine clearance or special tests for renal function
c. Thyroid function tests
d. Hepatic function tests

D. Special diagnostic procedures
1. Cardiac fluoroscopy
2. Echocardiogram
3. Graphic recordings of phonocardiogram, apex cardiogram, arterial pulse, venous pulse
4. Cardiac catheterization
5. Venous pressure
6. Stress testing
7. Lung scan
8. Pulmonary angiogram

III. *Basic medical management*
A. Special care unit
1. None
2. Intensive care
B. Therapy, medical
1. Usual
a. Sodium restriction
b. Drugs
2. Occasional
a. Thoracentesis
C. Therapy, surgical
1. Usually none
2. May require palliative cardiac surgery

IV. *New or additional diagnosis (e.g., complications)*
A. Pulmonary embolization
B. Myocardial infarction
C. Pneumonia
D. Renal insufficiency and/or electrolyte imbalance
E. Arrhythmia
F. Valvular disease

V. *Consultations*
A. None
B. Internal medicine/cardiology
C. Cardiovascular surgery

VI. *Length of hospital stay (with applicable modifiers)*
Range 1 day–indefinite

VII. *Factors modifying standard care*
- A. Pulmonary embolization
- B. Myocardial infarction
- C. Pneumonia
- D. Renal insufficiency and/or electrolyte imbalance
- E. Arrhythmia
- F. Valvular disease

DIAGNOSIS:
ATRIAL FIBRILLATION

I. *Indications for admission*
- A. Newly discovered—for possible conversion to sinus rhythm
- B. Rapid rate requiring prompt slowing
- C. Failure to respond to ordinary therapy
- D. Unusual etiology suspected (e.g., thyrotoxicosis, anemia)
- E. Severe hypotension, shock
- F. Heart failure
- G. Chest pain (angina, impending infarction)
- H. Syncope
- I. Embolization

II. *Criteria for diagnosis*
- A. History
  Symptomatology referable to:
  1. The underlying disorder
  2. Atrial fibrillation per se (e.g., palpitations)
  3. Complications of the rapid rate (failure, coronary insufficiency)
  4. None
- B. Physical findings
  1. Cardiovascular findings other than atrial fibrillation (that of underlying disease)
  2. Apical and radial rates—pulse deficit
  3. Absence of *A* waves
  4. Irregular apical and radial pulse
- C. Laboratory tests
  1. Usual
     a. Electrocardiogram
     b. Chest X-ray
     c. Other tests necessary to diagnose underlying etiology
  2. Occasional
     a. Cardiac fluoroscopy
     b. Echocardiogram
- D. Special diagnostic procedures
  1. None for atrial fibrillation, per se
  2. Intracardiac electrocardiogram (occasionally)

III. *Basic medical management*
- A. Special care unit
  May be used if complicated by shock, chest pain, heart failure
- B. Therapy, medical
  1. Usual
     Drug therapy
  2. Occasional
     Cardioversion (electrical)
- C. Therapy, surgical
  None

IV. *New or additional diagnosis (e.g., complications)*
- A. Shock
- B. Chest pain (angina → infarction)
- C. Congestive failure
- D. Embolization

V. *Consultations*
Internal medicine/cardiology

VI. *Length of hospital stay (with applicable modifiers)*
Range 1–21 days

VII. *Factors modifying standard care*
Complications as indicated in #IV
- A. Unusual etiology
- B. Shock
- C. Chest pain (angina → infarction)
- D. Congestive failure
- E. Embolization

DIAGNOSIS:
VALVULAR HEART DISEASE (MITRAL)

I. *Indications for admission*
- A. Presence of asymptomatic mitral disease (for study)
- B. Heart failure
- C. Complications

II. *Criteria for diagnosis*
- A. History
  1. No symptoms
  2. Dyspnea
  3. Palpitations
  4. Swelling of ankles
  5. Hemoptysis
- B. Physical findings
  1. Murmurs of mitral valve disease
  2. Opening snap (mitral stenosis)
  3. Signs of cardiac failure
  4. Actuated S_1 (mitral stenosis)
  5. Parasternal lift
- C. Laboratory tests
  1. Usual
     a. Electrocardiogram
     b. Chest X-ray
  2. Occasional
     Echocardiogram
- D. Special diagnostic procedures
  1. Cardiac catheterization
  2. Angiocardiography
  3. Graphic recordings
  4. Coronary arteriography (when clinically indicated)

III. *Basic medical management*
- A. Special care unit
  1. Severe cardiac failure
  2. Tachyarrhythmia
  3. Pulmonary embolus
- B. Therapy, medical
  Drug therapy
- C. Therapy, surgical
  1. Mitral valvotomy
  2. Valvuloplasty
  3. Valve replacement

IV. *New or additional diagnosis (e.g., complications)*
- A. Arrhythmias—especially atrial fibrillation
- B. Bacterial endocarditis
- C. Systemic embolization
- D. Severe hemoptysis
- E. Pulmonary embolism
- F. Pulmonary hypertension
- G. Heart failure

V. *Consultations*
1. Internal medicine/cardiology
2. Cardiovascular surgeon
3. As may be required by #4.

VI. *Length of hospital stay (with applicable modifiers)*
Range 1–24 days

VII. *Factors modifying standard care*
- A. Arrhythmias, especially atrial fibrillation
- B. Bacterial endocarditis
- C. Systemic embolization
- D. Severe hemoptysis
- E. Pulmonary embolism
- F. Pulmonary hypertension
- G. Heart failure

DIAGNOSIS:
VALVULAR HEART DISEASE (AORTIC)

I. *Indications for admission*
- A. Presence of asymptomatic severe aortic disease (for study)
- B. Heart failure
- C. Complications
- D. Chest pain
- E. Dizziness or syncope

II. *Criteria for diagnosis*
- A. History
  1. No symptoms
  2. Dyspnea
  3. Chest pain
  4. "Fainting"
  5. Dizziness
  6. Swelling of ankles
- B. Physical findings
  1. Characteristic murmurs of aortic valve disease
  2. Changes in character of arterial pulse
  3. Evidence of cardiac failure may be present
  4. Aortic thrill
- C. Laboratory tests
  1. Usual
     a. Electrocardiogram
     b. Chest X-ray
  2. Occasional
     a. Echocardiogram
- D. Special diagnostic procedures
  1. Cardiac catheterization
  2. Angiocardiography
  3. Graphic recordings
  4. Coronary arteriography (when clinically indicated)

III. *Basic medical management*
- A. Special care unit
  Aortic stenosis with cardiac failure may require management in intensive care units
- B. Therapy, medical
  Drugs
- C. Therapy, surgical
  Aortic valve surgery (usually valve replacement)

IV. *New or additional diagnosis (e.g., complications)*
- A. Arrhythmias
- B. Bacterial endocarditis
- C. Thromboembolism
- D. Postsurgical complications
- E. Progressive angina or myocardial infarction
- F. Heart failure

V. *Consultations*
- A. Internal medicine/cardiology
- B. Cardiovascular surgeon
- C. As may be required by #IV

VI. *Length of hospital stay (with applicable modifiers)*
Range 1–24 days

VII. *Factors modifying standard care*
- A. Arrhythmias
- B. Bacterial endocarditis
- C. Thromboembolism
- D. Postsurgical complications
- E. Progressive angina or myocardial infarction
- F. Heart failure

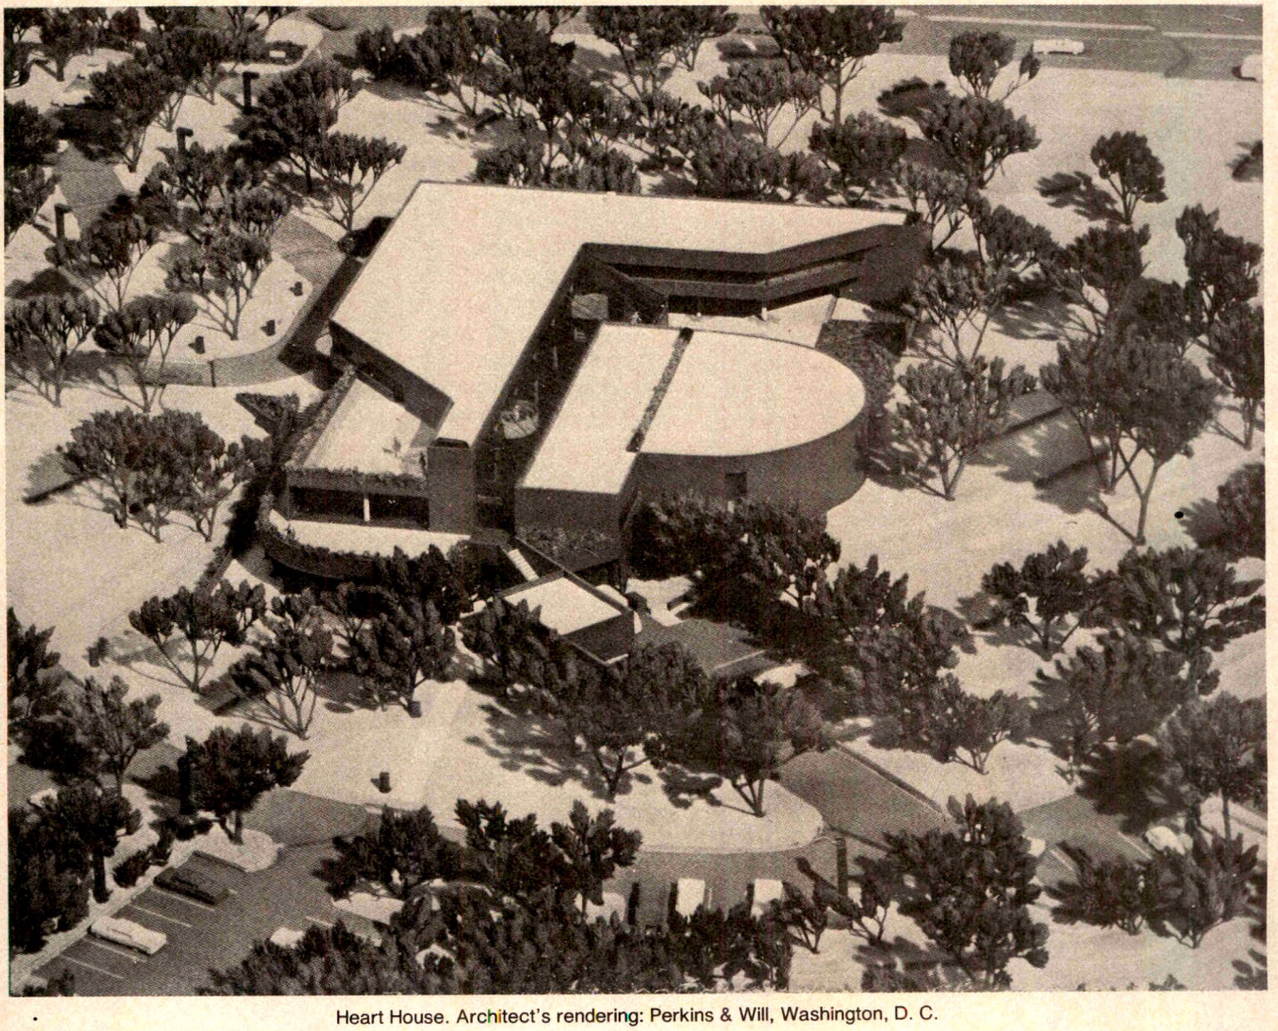
President's Page

In my last letter I indicated that future letters would be devoted to problems of personal concern to the Members of the College and cardiologists in general. Thus, I should like to discuss in some detail Heart House, which is to be built in Bethesda, Maryland.

My first reaction several years ago to Heart House was negative. After all, Bethesda is a long way from Houston. As Chairman of a Department of Medicine, I thought that we did a pretty good job in helping to meet the continuing education needs of physicians. In addition, I was already committed to about as much "charity" as I could afford and we were in the midst of a large local fund raising campaign in Houston. Finally, it looked as though the present recession (despite what the Administration wishes to call it) was inevitable. Construction costs were too high and were rising constantly. It therefore seemed foolhardy to consider trying to raise $5 million for a building and equipment and another $2 million for an endowment.

Nevertheless, I listened to Dwight Harken, Bill Martz, Grey Dimond, Forrest Adams, Don Dupler, Sam Fox, George Griffith, Bob Oblath, Bill Likoff, Ken Kohlstaedt, Bill Sodeman, Jeremy Swan, Suzanne Knoebel, Charles Fisch, Bill Roberts, Simon Dack and many others talk about the advantages; finally, I reexamined my thinking. I became convinced that Heart House will be one of the most important accomplishments that the American College of Cardiology has ever undertaken; furthermore it can be one of the most important things that will happen to American medicine during the present decade.

Heart House is not to be just an office building to house the headquarters and administrative functions of the Col-



Heart House. Architect's rendering: Perkins & Will, Washington, D. C.

lege. If that was all we needed, with construction costs as they are, it would be more economical to rent office space in Bethesda. But Heart House is to be a Learning Center. It is to be the hub of cardiovascular continuing education for American medicine.

There will be a Classroom for 60 students with comfortable seats equipped with individual stethophones, monitors for easy viewing of physiologic data and other parameters, and terminals for student response systems. The seats will be located so as to afford easy viewing of patients and other demonstrations and easy informal communication with the instructor. The classroom will be able to accommodate up to 120 for more formal presentations. There will be a Library with current journals and texts and ready access to the National Library of Medicine and the facilities of the proposed Lister Hill Center for Medical Communication. In fact, Heart House might be considered an outreach or an entrance to these institutions as well as the National Institutes of Health and the Federal Medical School to be constructed shortly on the campus of the U. S. Naval Hospital at Bethesda. Heart House will be within 1 mile of these facilities. There will be individual study carrels where the student can study, at his own pace, prepared material on all aspects of cardiology. In addition, there will be six conference rooms that will permit informal workshops or seminars.

Heart House will have the capabilities for closed-circuit television and planning and producing video teaching aids, self-assessment examinations, and the like. It will become the center for activities to identify what is important for the practicing cardiologist to learn, how he can best learn and how he can retain and use what he learns. It will also house the College headquarters.

It is obvious that if the Learning Center can accommodate only 120 students at most, and if it is located in Bethesda, it will take many years to accommodate all of the members and friends of the College. It might appear, therefore, to offer little to the members in Texas, Iowa, Washington State and Florida.

But the Learning Center is just that. It is a Center where the major emphasis is to be on learning. It is planned that we will have programs for members and other physicians to help with their teaching as well as learning techniques. The thoughtful physician knows that the best way to learn is to teach. The Center will develop techniques for programs that can be presented in Texas, Iowa, Washington State and Florida. Heart House will be a Learning Center for catalyzing learning of cardiology throughout the country.

One might ask, Is this function not being carried out by the medical schools? The answer is a guarded "Yes, but" . . . the medical schools have limited facilities . . . they have limited personnel compared to the membership of the American College of Cardiology. Actually, the College can claim faculty members from 114 medical schools. More importantly the College has enormous input from practicing cardiologists and cardiovascular surgeons, and other specialists. Thus, the program, the learning, will be more relevant to patient care. But the College will continue to conduct its 2 to 5 day programs throughout the country in conjunction with medical schools and teaching centers as in the past. As a result of what has been presented at the Learning Center, these programs will be better.

Being located near Washington and the Capitol, Heart House will have a profound effect on national planning for health, not just for cardiology, but for the whole field of medicine. It will become a home for the successful Bethesda conferences that have been conducted in the past by the College and have had a profound effect on a number of aspects of medicine.

For these and other reasons I became an enthusiastic supporter of Heart House. I pledge that during this year, while I am President, we will raise the necessary money so as to break ground, and we *will* break ground for Heart House in Bethesda. But in order to accomplish this, I need your help.

Under the leadership of Dwight Harken and his Campaign Funds Committee, as of February 28, 1974, $1,710,434 has been pledged. There are 256 Founders and 60 Benefactors. A Founder has pledged $1,000 over 3 years or less and a Benefactor, $3,000. This represents only a dollar a day or $3 a day for 3 years. That is a small price to pay.

But we have a long way to go. It is imperative that we get 1,000 more Founders or Benefactors. If you are not already one, won't you become one? Or if you are already a Founder, won't you move up and become a Benefactor?

In addition, we are seeking 400 members for the "Order of William Harvey." These members will agree, in addition to their present contributions, to raise $4,000 from patients, other fellows, other members, industry, foundations and other sources. We are preparing a special packet of information for those who agree to join the "Order of William Harvey" which will include pledge cards, literature and a small plaque describing the program for the office waiting room. The members of the "Order of William Harvey" will be recognized on a special plaque in Heart House and by certificates suitable for framing. They will have a special name badge and be invited to a special reception at the next ACC meeting in Houston. They will indeed be a select group in the life of the College for collectively they will have raised over $2 million.

Fifty thousand dollars was raised by a small group of members who worked very diligently at the last annual meeting of the ACC in New York. The efforts of this group served to spawn the idea of organizing the "Order of William Harvey." As a result of efforts in New York, the following, along with other "workers," are designated charter members of the "Order of William Harvey":

William B. Abrams, MD, New Jersey
Louis F. Bishop, MD, New York
Eliot Corday, MD, California
Simon Dack, MD, New York
E. Grey Dimond, MD, Missouri
Leonard S. Dreifus, MD, Pennsylvania
Donald A. Dupler, MD, Pennsylvania
George C. Griffith, MD, California
Rolf M. Gunnar, MD, Illinois
Dwight E. Harken, MD, Massachusetts
Suzanne B. Knoebel, MD, Indiana
Kenneth G. Kohlstaedt, MD, Indiana
Seymoure Krause, MD, Pennsylvania
William Likoff, MD, Pennsylvania
Henry D. McIntosh, MD, Texas
Oscar Magidson, MD, California
B. L. Martz, MD, Missouri
Robert W. Oblath, MD, California
Henry I. Russek, MD, New York
H. J. C. Swan, MD, California
Sylvan L. Weinberg, MD, Ohio

Won't you become a Founder or a Benefactor as well as a member of the "Order of William Harvey?" Please fill in

the attached pledge card and mail it to the College Office. It should be obvious that we would welcome larger contributions. For example, one may have a chair in the Classroom named in honor of oneself, a respected colleague, teacher or loved one for $6,300; larger contributions can qualify for designating seminar rooms and other areas.

Finally, why am I so concerned about Heart House becoming a reality? Why should you be? It is obvious that continuing education is a must for the busy practitioner. Self-assessment examinations and recertification examinations will become a way of life. The Board of Medical Specialists has recently indicated that voluntary periodic recertification examinations have been formally approved by 19 of 22 specialty boards. One board, the American Board of Family Practice, has made periodic recertification mandatory. Thus we cannot escape any longer demands of the public for evidence of continuing education and competence in patient care. Those of us who do not have boards should not fear if we continue to learn and "keep up." Heart House will ensure that self-assessment and examination techniques will be available for noncertified physicians so that they can assure the public that they are knowledgeable in the latest that the science of medicine can offer.

Thus, Heart House is a personal necessity for all of us who care for patients.

Henry D. McIntosh, MD, FACC
President
American College of Cardiology

1974–75 Committee Appointments

The following physicians have been named to the College Committees listed below:

ADMINISTRATIVE COMMITTEES

Awards Committee

Forrest H. Adams, Chairman, 1976
California
C. Richard Conti, 1977
Maryland
W. Proctor Harvey, 1976
District of Columbia
Thomas N. James, 1976
Alabama
Hilliard J. Katz, 1975
California
T. Joseph Reeves, 1977
Texas

Budget, Finance and Investment Committee

Warren J. Taylor, Chairman, 1975
Massachusetts
Melvin D. Cheitlin, 1976
Maryland
John J. Curry, 1975
Maryland

Constitution and Bylaws Committee

Robert W. Oblath, Chairman, 1976
California
Robert C. Tarazi, 1977
Ohio
Robert E. Whalen, 1977
North Carolina

Credentials Committee

Dean T. Mason, Chairman, 1976
California
L. Julian Haywood, 1975
California
Dan G. McNamara, 1976
Texas
Peter V. Moulder, 1975
Florida
Walt F. Weaver, 1976
Nebraska

Executive Committee

Henry D. McIntosh, Chairman, 1976
Texas
Charles Fisch, 1977
Indiana
William Likoff, 1975
Pennsylvania
Edward S. Orgain, 1975
North Carolina
H. J. C. Swan, 1975
California
Warren J. Taylor, 1975
Massachusetts

Government Relations Committee

Sylvan L. Weinberg, Chairman, 1976
Ohio
William A. Sodeman, Vice Chairman, 1975
Pennsylvania
Arthur C. Beall, Jr., 1976
Texas
David B. Carmichael, Jr., 1976
California
Samuel M. Fox, III, 1976
District of Columbia
Laurence A. Grossman, 1976
Tennessee
Herman K. Hellerstein, 1975
Ohio
George V. Irons, Jr., 1977
North Carolina
James A. Kaufmann, 1977
Georgia
John M. Packard, 1975
Alabama
Robert L. VanCitters, 1975
Washington

Long Range Planning Committee

Charles Fisch, Chairman, 1975
Indiana
Walter H. Abelmann, 1976
Massachusetts
Arthur C. Beall, Jr., 1975
Texas
Henry W. Blackburn, Jr., 1975
Minnesota
E. Grey Dimond, 1975
Missouri
Robert S. Eliot, 1975
Nebraska
Mary Allen Engle, 1976
New York
Robert J. Hall, 1977
Texas
Dean T. Mason, 1976
California
Robert W. Oblath, 1976
California
Warren J. Taylor, 1975
Massachusetts

Membership Committee

Seymoure Krause, Chairman, 1977
Pennsylvania
Paul E. Ebert, 1975
New York
Ralph Eugene Smith, 1976
Minnesota

Nominating Committee

Robert O. Brandenberg, 1975
Minnesota
Samuel M. Fox, III, 1976
District of Columbia

Oscar Magidson, 1976
California
Charles E. Rackley, 1977
Alabama
David C. Sabiston, Jr., 1977
North Carolina

VIIth WORLD CONGRESS OF CARDIOLOGY

The VIIth World Congress of Cardiology will be held in Buenos Aires, Argentine Republic, September 1 to 7, 1974. The Buenos Aires Sheraton Hotel will be the headquarters for sessions and exhibitions.

The scientific meetings will consist of Principal Sessions, Round Tables, Conferences, Free Communications, Luncheon Panels and Talks with Experts. In addition to the scientific program and scientific, commercial and industrial exhibitions, a full social program with scheduled tours and visits to museums and shows has been planned.

For further information, write the Secretary General, Dr. Bernardo Malamud, Avda. Roque S. Peña 1110, 2º piso, Buenos Aires, Argentina. Cables: CENIBAIRES.

A PRACTITIONER'S APPROACH TO ANGINA IN 1974

MORNING SESSION: 9:00 AM TO 12 NOON

Angina Pectoris

Introduction

William J. Grace, MD, Director of Medicine, St. Vincent's Hospital; Professor of Clinical Medicine, New York University School of Medicine, New York, New York.

Pain Patterns in Angina Pectoris. Clinical Clues to a Bedside Diagnosis.

John R. Tobin, Jr., MD, Professor and Chairman, Department of Medicine, Loyola University Stritch School of Medicine, Maywood, Illinois.

Auscultatory and Electrocardiographic Manifestations of Coronary Artery Disease.

James V. Talano, MD, Assistant Professor of Medicine and Assistant Director, Cardiac Catheterization Laboratory. Loyola University Stritch School of Medicine, Maywood, Illinois.

Anatomic and Angiographic Features of Coronary Artery Disease.

William Towne, MD, Assistant Director Cardiac Catheterization Laboratory, Veterans Administration Hospital, Hines, Illinois. Instructor in Medicine, Loyola University Stritch School of Medicine, Maywood, Illinois.

Break

Localization of the Atherosclerotic Plaque in Coronary Artery Disease.

Gissur Brynjolfsson, MD, Professor and Chairman, Department of Pathology, Loyola University Stritch School of Medicine, Maywood, Illinois.

A Physiologic Approach to Angina Pectoris.

Henry S. Loeb, MD, Associate Program Director, Section of Cardiology, Veterans Administration Hospital, Hines, Illinois. Associate Professor of Medicine, Loyola University Stritch School of Medicine, Maywood, Illinois.

Panel Discussion and Questions

Lunch

AFTERNOON SESSION: 1:00 PM TO 5:00 PM

Modern Approach to the Patient with Angina Pectoris

Management of Risk Factors and Pattern of Lipoprotein and Abnormalities in the Patient with Angina Pectoris.

David M. Berkson, MD, Associate Professor, Department of Community Health and Preventive Medicine, Northwestern University Medical School, Chicago, Illinois.

Use of Exercise Stress Testing in the Evaluation of the Patient with Chest Pain: Reliability and Safety.

John F. Moran, MD, Director of Graphic Laboratory and Assistant Professor of Medicine, Loyola University Stritch School of Medicine, Maywood, Illinois.

Syndromes Which Mimic Angina Pectoris and Their Management.

Rimgaudas Nemickas, MD, Associate Chief Section of Cardiology and Associate Professor of MEDICINE= Loyola University Stritch School of Medicine, Maywood, Illinois.

An Approach to the Medical Management of Stable Angina Pectoris.

Leon Resnekov, MD, Joint Director, Section of Cardiology and Professor of Medicine, University of Chicago Hospitals, Chicago, Illinois.

Panel Discussion

Break

Management of the Patient with Pre-Infarction Angina; Indications and Risk of Angiography.

Patrick J. Scanlon, MD, Director, Catheterization Laboratory and Assistant Professor of Medicine, Loyola University Stritch School of Medicine, Maywood, Illinois.

Follow-up of Patients Undergoing Coronary Artery Surgery for Angina Pectoris.

Roque Pifarre, MD, Chief, Cardiac Surgery Section and Professor of Surgery, Loyola University Stritch School of Medicine, Maywood, Illinois. Chief, Cardiopulmonary Surgical Section, Veterans Administration Hospital, Hines, Illinois.

When is Surgery Indicated in the Patient with Coronary Artery Disease?

Rolf M. Gunnar, MD, Chief, Section of Cardiology and Professor of Medicine, Loyola University Stritch School of Medicine. Program Director, Section of Cardiology, Veterans Administration Hospital, Hines, Illinois.

The Natural History of Angina Pectoris: An Overview of the Problem.

Oglesby Paul, MD, Professor of Medicine, Northwestern University Medical School, Chicago, Illinois.

Panel Discussion

For further information write American College of Cardiology, 9650 Rockville Pike, Bethesda, Md. 20014.
ogy, 9650 Rockville Pike, Bethesda, Md. 20014.

Calendar of Continuing Medical Education Programs

The National Committee for Continuing Medical Education, William Likoff, MD, FACC, Chairman, announces the following calendar of programs.

Each program is designed to enlarge knowledge and clarify the endlessly changing frontiers which mark scientific achievements in the recognition and treatment of cardiovascular disease. Although the disciplined objective of each program as well as its content, format and faculty are primarily determined by the Program Director, the National Committee for Continuing Medical Education always exercises the prerogative of final review and approval, whether the program is sponsored solely by the College or in collaboration with universities, colleges, hospitals and other professional societies.

Subject matter reflects national interest and needs in the fields of patient care, research and teaching. The program structures vary in method of education.

The National Committee for Continuing Medical Education of the College earnestly solicits the interest of member and nonmember physicians alike in continuing education for the clear reason that participation provides a unique opportunity to deepen one's understanding of heart disease, the most formidable and challenging health problem of our time.

Programs and faculty are subject to change. For further information write Mary Anne McInerny, Director, Department of Continuing Education Programs, American College of Cardiology, 9650 Rockville Pike, Bethesda, Md. 20014.

MAY AND JUNE, 1974

MAY 6–9 **The Recognition and Management of Coronary Syndromes.** J. Willis Hurst, FACC and Robert C. Schlant, FACC, directors. Royal Coach Motor Hotel, Atlanta, Ga.

MAY 9–11 **The Ventricular Ectopic Beat: Heart-throb or Harbinger of Death.** Bernard Tabatznik and J. O'Neal Humphries, FACC, directors. Cross Keys Inn, Baltimore, Md.

MAY 15–17 **Clinical Auscultation of the Heart.** W. Proctor Harvey, FACC, director. Georgetown University School of Medicine, Washington, D. C.

MAY 17–19 **Core Curriculum: Rational Drug Therapy in Cardiovascular Disease.** Robert J. Lee, PhD., director. The Nassau Inn, Princeton, N. J.

MAY 23–25 **Cardiologist's Appraisal of Operable Heart Disease.** Arthur Selzer, FACC and Keith E. Cohn, FACC, directors. St. Francis Hotel, San Francisco, Calif.

JUNE 6–8 **Core Curriculum in Echocardiography: New Developments in Cardiac Ultrasound.** Arthur D. Hagan, director and Robert A. O'Rourke, FACC, co-director. Town and Country Hotel, San Diego, Calif.

INSTRUCTIONS FOR AUTHORS

The editors and publishers of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- **Address manuscript** to Simon Dack, MD, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- **Submit two copies** of all elements of the article: text, references, legends, tables and figures.
- **Arrange the paper** in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- **Number all pages** in above sequence, beginning with title page as 1, abstract as 2, etc.
- **Type all matter:** (1) on 8½ × 11 opaque white bond paper; (2) in duplicate; (3) on **one side** of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- **Number title page** as page 1.
- **Include first names,** degrees and, where applicable, FACC for all authors.
- **Insert at bottom:** name and address of institution from which work originated plus information about grants.
- **Add at bottom** the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- **Limit words as follows:** 100 to 250 words for major articles; 50 to 100 words for case reports.
- **Add at end of abstract:** an alphabetical list of 2 to 6 key words and subjects for indexing.

THE TEXT

- **Number pages** in sequence after abstract.
- **Type in duplicate;** double-space.
- **Do not use abbreviations** such as SVC, WPW: write out; superior vena cava, Wolff-Parkinson-White.

Abbreviate measurements (mm, kcal and the like) as recommended in the Style Manual for Biological Journals, American Institute of Biological Sciences, 3900 Wisconsin Avenue, N.W., Washington, D. C.

- **Cite in numerical** order every reference, figure and table. (Order of mention in text **determines the number** given to each.)
- **Place acknowledgments** at end of text, before references.

THE REFERENCES

- **Type in duplicate;** double-space.
- **Place immediately** after text, and number pages in sequence after text page numbers.
- **Number the references** in order in which they are mentioned in text.
- **Follow the general** arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- **Start at top** of new page.
- **Type in duplicate;** double-space.
- **Number pages** in sequence after last page of references.
- **Identify at** the end of each legend and **in alphabetical order** all abbreviations in the figure described.

THE TABLES

- **Start each** table at top of new page.
- **Type in duplicate;** double-space.
- **Number pages in** sequence after last page of legends.
- **Give each table** a number (in roman numerals: Table I, II, etc.) and a title. Number the tables in order in which they are mentioned in the text.
- **Provide a footnote** to each table—identifying **in alphabetical order** all abbreviations used.

THE FIGURES

- **Submit 2 glossy prints** (not originals) of each photo and drawing.

Please note that art work of published articles will not be returned.

- **Use black ink** for all charts (line drawings). Make decimals, broken lines, etc. strong enough for reproduction.
- **Use arrows** to designate special features.
- **Crop photomicrographs** to show only essential field.
- **Identify figures** on back by number and author's name.
- **Number figures** in order in which they are mentioned in the text.
- **Indicate top** of each figure.
- **Submit written permission** from publisher and author to reproduce any previously published figures.
- **Limit figures** to number necessary for clarity. The publisher allows a limited sum toward reproduction.

Examples of Styles of References

For periodicals, follow INDEX MEDICUS:

31. Bellet S, Feinberg LJ, Sandberg H, et al: The effects of caffeine on free fatty acids and blood coagulation parameters of dogs. J Pharmacol Exp Ther 159: 250-254, 1968

(Author: please note that no periods are used after authors' initials.)

For books (edited by other than author of article):

28. Schiebler GL, Van Mierop LHS, Krovetz LJ: Diseases of the tricuspid valve, chap 20. In, Heart Disease in Infants, Children and Adolescents (Moss AJ, Adams F, ed). Baltimore, Williams & Wilkins, 1968, p 134

For books (with identical author and editor):

36. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26

(Author: all book references should have specific page numbers)

The newest Ekoline 20A® features multi-parameter capability.

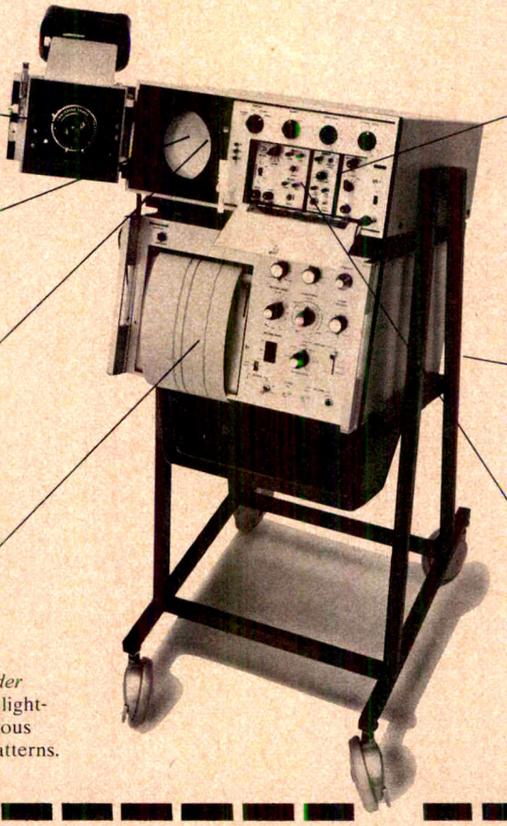
Two new modules give the Smith Kline Instruments Ekoline 20A® an unmatched multi-trace capability. The Isolated Sweep/EKG Module and the Multi-Parameter Amplifier Module enable the E20A Ultrasonoscope to produce traces for ultrasound, EKG, phono and carotid pulse or apex. Combine this with the Fiber-optic Recorder and the result is high quality, grey scale strip chart recordings of pertinent information—at a surprisingly low cost.

1. *New Oscilloscope Camera* features built-in electronic shutter release, uses high-speed 'Polaroid' film.

2. *New High-Resolution Oscilloscope* is standard on all 'Ekoline 20A' instruments, gives outstanding display of all echo patterns.

3. *New Long-Persistence Oscilloscope,* available as optional equipment, uses P7 phosphor to provide best possible display of M-mode echo patterns.

4. *New Fiber-Optic Line-Scan Recorder* utilizes fiber-optic CRT to expose light-sensitive paper, producing continuous "strip-chart" recordings of echo patterns.



5. *New Isolated Sweep/EKG System* Converts A-Mode echo display from a moving organ into M-Mode display. Features isolated, linear, and movable EKG.

6. *New Equipment Cart* conveniently houses 'Ekoline 20A' and Recorder. Permits complete system to be readily moved to any location throughout the hospital.

7. *New Multi-Parameter Amplifier Module* provides the capability for echo, EKG, phono and carotid pulse or apex traces.

REQUEST FOR ADDITIONAL INFORMATION

Please:

☐ Have representative call me to arrange a demonstration.

☐ Send detailed literature.

The Model 5000 Dyna-Gram® Recorder for Holter Electrocardiography.

The Model 5000 is a new 24-hour cassette recorder with electronic timing and a digital patient clock for precise correlation of the ECG with patient activities and symptoms. The advanced design of the Model 5000 includes an exclusive circuit to minimize electrode artifact. The rechargeable Dyna-Gram® Power-Pack provides continuous 24-hour recording capability *without* turning the cassette. Compact and light weight, the Model 5000 Dyna-Gram® Recorder can be worn with a waist belt or a shoulder strap.

No purchase of costly processing equipment is required. Your recorded Dyna-Gram® cassettes will receive Cardio-Dynamics comprehensive analysis using the unique Dyna-Gram® III Analyzer System.

A quality line of cassettes, disposable electrodes, and related patient hookup supplies is available.

Bright new talk show

We've just come out with a series of patient monitoring modules that are completely new. From their brighter digital displays to their broader capabilities, they talk to you loud and clear.

First the digital displays.

Characters are more than a ½ inch high, and they form solid lines of light which are easily readable across a room or down a corridor.

They flash HI, LO and OFF (in response to high and low alarms and leads off) and, of course, numerical values.

All alarm set points can be read directly on the digital display, improving the accuracy of the setting.

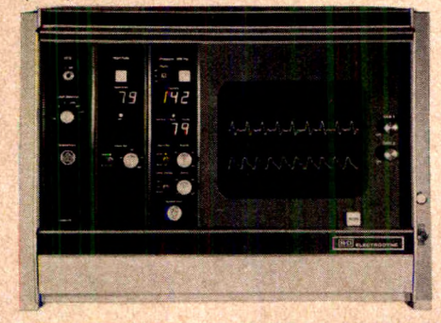
Displays can be darkened at night so as not to disturb a patient. In the event of an alarm, they automatically re-appear.

Now for capability.

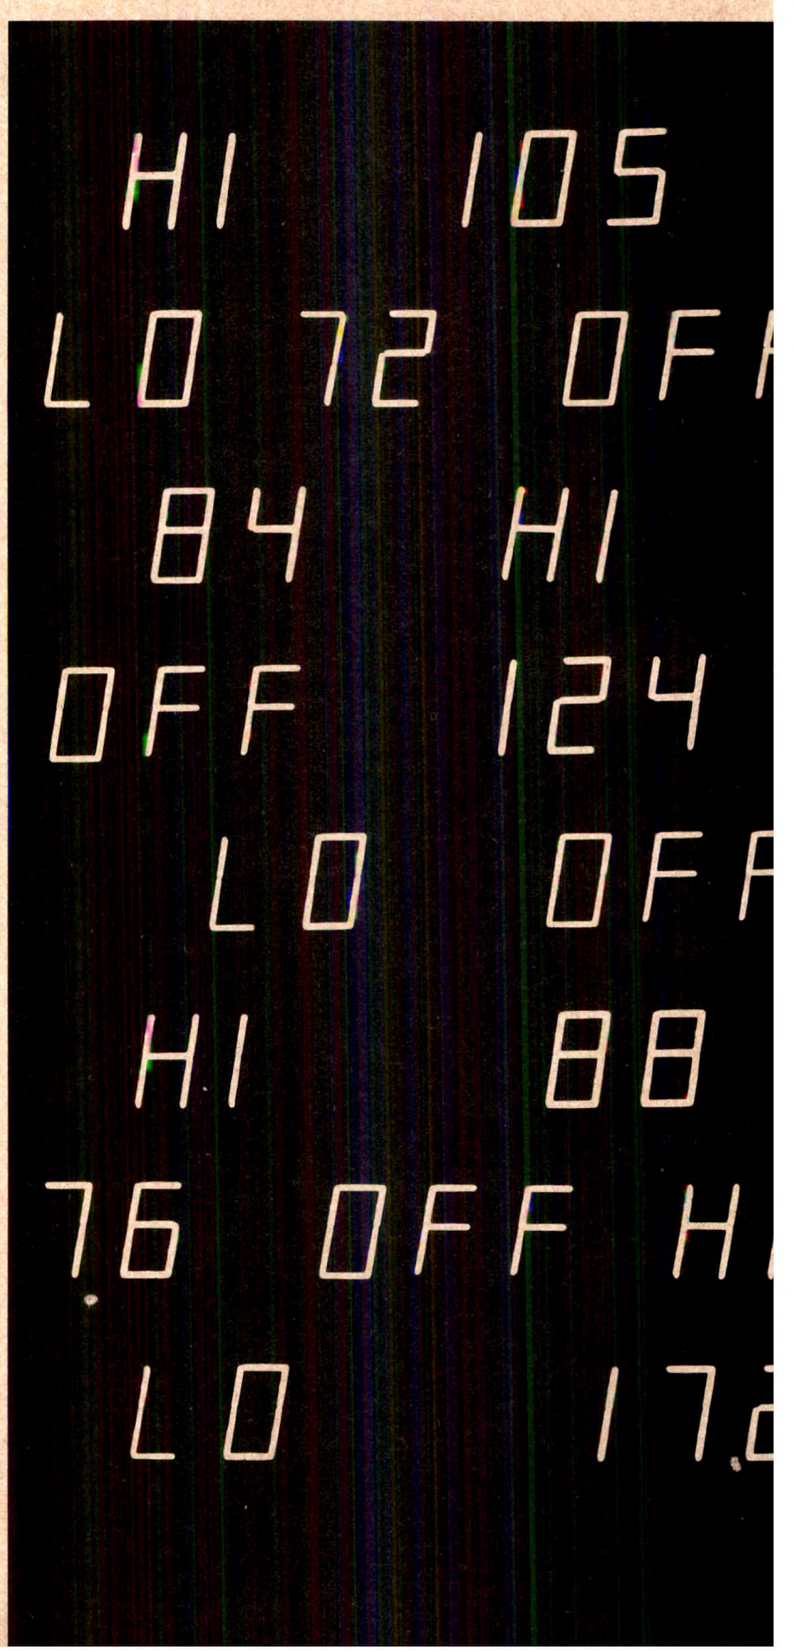
Our HR-3 Digital Heart Rate Module is physically independent of the ECG amplifier and can be placed at bedside, central station, or both. It monitors heart rate and eliminates artifacts. It even ignores pacemaker spikes when used with B-D Electrodyne's new ECG amplifier.

Our PR-18 Digital Pressure Module processes and provides two displays to show systolic and diastolic or mean pressures simultaneously. It also has adjustable high and low settings for each pressure. All in one module.

So now you have a lot more reasons for looking into a B-D Electrodyne monitoring system. And if you're using one of ours right now, these new B-D Electrodyne digital modules will fit right in. Remember: one thing you *don't* buy from B-D Electrodyne is obsolescence. Why not send for details? B-D ELECTRODYNE, Division of Becton, Dickinson and Company, Sharon, Massachusetts 02067 (617) 828-9080.



B-D **ELECTRODYNE**
Division of Becton, Dickinson and Company



B-D AND ELECTRODYNE ARE TRADEMARKS OF BECTON, DICKINSON AND COMPANY

We'll lend your patient an ear... and you a hand.

Cardio-Dynamics Comprehensive Analysis of Holter Recordings for
- **Clinical Practice • Research**
- **Drug Evaluation**
- **Multiphasic Screening**

Your Holter recordings are processed by skilled Cardio-Dynamics analysts using the new and unique Dyna-Gram® III Analyzer System. Without having to purchase costly scanning equipment, you receive fast direct-mail service throughout the USA-including a telephone report of potentially ominous phenomena.

Cardio-Dynamics exclusive Dyna-Gram® Report gives counts of all ectopics *by morphology,* along with ECG strip documentation of each morphology. The Dyna-Gram® Report allows you to separately evaluate early cycle and late cycle ventricular ectopics, as well as any differential response to therapy.

Complete Holter ECG analysis is available for recorded cassettes from Cardio-Dynamics new 24-hour Model 5000 Dyna-Gram® Recorder, or for Avionics reel recordings.

You expect a lot from a pacemaker with a 36 month full replacement warranty.

And you get a lot from the IDP-54:

An implantable R-wave-inhibited pacemaker for intracardial and myocardial stimulation for a low, constant stimulation threshold.*

Low energy consuming circuitry and the new Mallory cell producing up to 4 to 5 years operating life.

36 month full replacement warranty.

Suitability for initial implant or implantation in patients with existing implanted electrode systems.

* The implantation of an R-wave-inhibited pacemaker has been well proven in the following cases: intermittent AV block with predominant sinus rhythm, recurrent bradycardia and second implantation to replace a fixed rate pacemaker with virtual return to sinus rhythm.

Get to know Biotronik, the pacemakers known for quality.

Laragh's Hypertension Manual

Edited by John H. Laragh, M.D., of the College of Physicians and Surgeons, Columbia-Presbyterian in New York.

A classic treatise for understanding, diagnosing and treating hypertension.

Chapters by:

- ☐ John Laragh on The Renin System in Causation and on Evaluation of Hypertensive Patients.
- ☐ Sir George Pickering on Definitions, Natural Histories and Consequences.
- ☐ Louis Tobian on Experimental Mechanisms
- ☐ Arthur Guyton on Control Mechanisms
- ☐ Edward Freis on Why, When, and How to Treat.
- ☐ Edward Biglieri on Diagnosis of Adrenocortical Hypertension
- ☐ Harriet Dustan on Hemodynamic Mechanisms
- ☐ Jay Cohn on Hypertension and the Heart
- ☐ Hans Brunner on Renin as a Risk Factor

Approximately 900 pages, 150 illustrations.
Price: $37.00
Ready January, 1974.

Partial list of contributors:

John H. Laragh	J. C. Hunt
Sir George Pickering	F. R. Buhler
E. A. Lew	E. G. Biglieri
E. D. Freis	D. R. LaBarthe
H. R. Brunner	K. Engelman
A. C. Guyton	J. E. Sealey
L. Tobian, Jr.	C. R. Ayers
H. P. Dustan	J. A. Wilber
J. N. Cohn	J. Koch-Weser
V. DeQuattro	P. Kincaid-Smith
J. Giese	F. A. Finnerty
A. R. Christlieb	E. D. Vaughan
A. F. Lever	

Dr. Laragh's Hypertension Manual will undoubtedly become the standard reference work in Hypertension. Use the attached form to place your order. This is the first in a series of Yorke Medical Books—from the publishers of The American Journal of Cardiology, The American Journal of Medicine, The American Journal of Surgery, and Cutis.

New Clinical Knowledge in the Mechanism,
Recognition and Therapy of Arrhythmias

Symposium on

ELECTROPHYSIOLOGIC CORRELATES OF CLINICAL ARRHYTHMIAS

Guest Editor: Charles Fisch, MD, FACC, Indiana University Medical Center

Contributions by prominent specialists from universities and medical centers across the country.

Presents examples of arrhythmias with mechanisms that have been deduced by analysis of clinical tracings and are being confirmed by electrophysiologic studies.

Originally published in the September, October and November 1971 issues of THE AMERICAN JOURNAL OF CARDIOLOGY—a $15.00 value—**now available to you under one cover for only $8.00.**

Papers include: Automaticity and Automatic Rhythms . . . The Concepts of Reentrant Activity Responsible for Ectopic Rhythms . . . Atrial Fibrillation . . . Ventricular Fibrillation . . . Atrioventricular Block . . . Aberrancy: Electrophysiologic Aspects . . . Exit Block . . . Concealed Conduction . . . Specialized Tissues and Preferential Conduction in the Atria of the Heart . . . Contribution of His Bundle Recordings to the Understanding of Clinical Arrhythmias . . . Wolff-Parkinson-White Syndrome. A New Look . . . Artificial Pacing of the Human Heart. BLOOD FLOW

for clinical applications

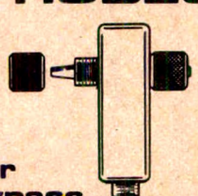
- Designed for clinical O.R. or cath lab use
- Easily applied handle-type probe
- Patient safety assured through isolation circuitry
- Simple to operate - minimum controls - direct readout in milliliters

FLOW PROBES

for clinical applications

- Convenient, handle-type probe with positive capture slide
- Designed for O.R. and cath lab use
- For rapid analysis of flow through exposed blood vessels
- Use with Biotronex clinical blood flowmeter

FLOW PROBES



for bypass applications

- Use with heart-lung machine, artificial kidney or similar systems
- Iron core construction provides high sensitivity and accuracy
- Operates with BLI research and clinical blood flowmeters
- Available in sizes to fit most tubing

Nitro-Bid® (nitroglycerin) therapy assists in the "total management" of your patient.

Nitro-Bid capsules reduce sublingual nitroglycerin requirements as they reduce the number of angina attacks . . . increase exercise tolerance.

The Third Step in Angina.*

After the classic "2-Step" Test aids in a diagnosis of angina, sustained-release Nitro-Bid® (nitroglycerin) is a logical third step. Here's why.

In angina secondary to arteriosclerotic heart disease, sustained-release

Sustained-release Nitro-Bid Plateau CAPS® provide a metered sequence of medication during the night to protect against nocturnal angina attack.

In titrating dosage, availability of different strengths "...is quite an asset..."[1]

Nitro-Bid 2.5 and Nitro-Bid 6.5 capsules afford two dosage strengths for convenience in increasing or decreasing dose to accommodate patient symptoms.

NITRO-BID® 2.5
(nitroglycerin 2.5 mg)
Plateau CAPS®

NITRO-BID® 6.5
(nitroglycerin 6.5 mg)
Plateau CAPS®

INDICATIONS

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

*"Possibly" effective:
For the management, prophylaxis or treatment of anginal attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Recent myocardial infarction, severe anemia, glaucoma, increased intracranial pressure, idiosyncrasy.
Precautions: For ORAL, not sublingual, use. If blurring of vision or dryness of mouth occurs, discontinue drug. Tolerance may develop on long-term usage.
Adverse Reactions: Occasional transient headaches. Overdose may cause flushing, headaches, tachycardia, dizziness.
Dosage: One capsule two or three times daily at 8 to 12 hour intervals.
Reference: 1. Master, AM: The management of angina pectoris. *Modern Medicine* **38**:92-100 (Feb 23) 1970.

Another patient benefit product from MARION PHARMACEUTICAL DIVISION MARION LABORATORIES, INC. KANSAS CITY MISSOURI 64137

"The drug of choice for oral replacement of potassium is potassium chloride solution."

AMA Drug Evaluations 1971, First Edition, Chicago, American Medical Association, p. 121.

Kay Ciel® Elixir is potassium chloride... tastes good too!

COMPOSITION: Each 15 cc. (one tablespoonful) contains potassium chloride 1.5 Gm., supplying 20 mEq. of elemental potassium, in a cherry-flavored, palatable base, alcohol 4%. Contains no sugar.
INDICATIONS: Treatment of potassium deficiency occurring especially during thiazide diuretic or corticosteroid therapy, digitalis intoxication, low dietary intake of potassium or as a result of excessive vomiting and diarrhea.
CONTRAINDICATIONS: Impaired renal function, untreated Addison's Disease, dehydration, heat cramps, and hyperkalemia.
PRECAUTIONS: Potassium chloride should be administered with caution and adjusted to the requirements of the individual patient, since the amount of deficiency and corresponding daily dose is often not known. Excessive or even therapeutic dosages may result in potassium intoxication. Patients should be frequently checked and periodic ECG and/or plasma potassium levels made. High plasma concentrations of potassium ion may cause cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease. In hypokalemic states, attention should be directed toward the correction of the frequently associated hypochloremic alkalosis.
SIDE EFFECTS: Vomiting, nausea, abdominal discomfort and diarrhea may occur. Symptoms and signs of potassium intoxication include listlessness, mental confusion, paresthesia of the extremities, weakness of the legs, flaccid paralysis, fall in blood pressure, cardiac arrhythmias, and heart block. When hyperkalemia exists, it should be promptly treated with the discontinuance of potassium administration or other steps to lower serum levels if indicated, since sudden shift in plasma levels may induce potentially dangerous cardiac arrhythmias.
DOSAGE AND ADMINISTRATION: Adults, one tablespoonful (15 cc.) diluted in one glass of water, twice daily after the morning and evening meal. Larger doses may be indicated according to the individual patient's requirements but should be administered under close supervision due to the possibility of potassium intoxication. Patients should be cautioned to follow directions explicitly in regard to dilution of Kay Ciel Elixir to prevent gastrointestinal injury.
HOW SUPPLIED: One pint and one gallon bottles.

Cooper Laboratories, Inc., Wayne, N.J. 07470/Ste. Therese, P.Q., Canada

If you test just for cholesterol in 10 passengers with hyperlipidemia

UNIVERSITY COLLEGE OF MEDICINE
LIBRARY
C. U.

4 may still be undetected

If you're not testing for triglycerides, as well as for cholesterol, you may detect only 6 out of 10 patients with hyperlipidemia.[1] Similarly, unless triglyceride status is considered in the selection of therapy, many patients may remain hyperlipidemic despite normalization of their cholesterol values. When you test for *both* triglycerides and cholesterol, chances are that you will detect more than 9 out of 10 patients (over 95%) with hyperlipidemia.[1] And the more hyperlipidemics you find, the more you can manage successfully.

Atromid-S (clofibrate) provides the needed dual lipid-lowering action
Because it helps reduce elevated cholesterol *and/or* triglyceride levels, ATROMID-S can be a valuable adjunct to diet in the treatment of patients with hypertriglyceridemia (Type IV) and pure hypercholesterolemia (Type IIa), as well as those with mixed hypercholesterolemia and hypertriglyceridemia (Types IIb, III and V hyperlipoproteinemia). See chart.

SUITABILITY OF ATROMID-S® (clofibrate)
FOR TREATMENT OF VARIOUS TYPES* OF HYPERLIPOPROTEINEMIA

Type	Estimated relative frequency (rounded to nearest %)[1]	Relative abnormalities of cholesterol and triglyceride concentrations[2]		Suitability of Atromid-S
		cholesterol	triglycerides	
II a	42%	++++		YES
II b		++++	++	YES
III	7%	+++	+++	YES
IV	42%	+	+++	YES
V	7%	+	++++	YES

*In Type I hyperlipoproteinemia, which represents approximately 2% of cases, no current drugs are effective.

Atromid-S®
Brand of clofibrate

helps reduce elevated cholesterol and/or triglycerides– not just cholesterol alone

IF GIVEN IN CONJUNCTION WITH ANTICOAGULANTS
WARNING: CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH ATROMID-S. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED USUALLY BY ONE-HALF (DEPENDING ON THE INDIVIDUAL CASE) TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS BEEN STABILIZED.

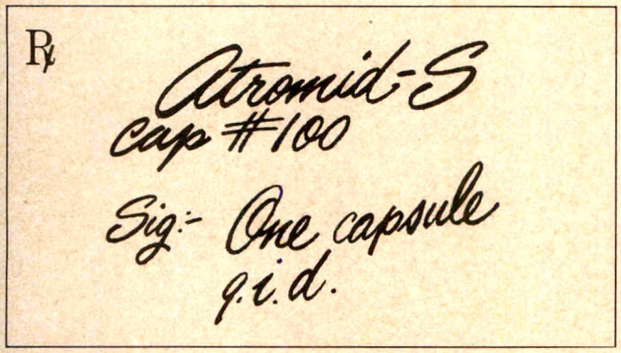
AN IMPORTANT NOTE: It has not been established whether the drug-induced lowering of serum cholester lipid levels has a detrimental, beneficial, or no effect on the morbidity or mortality due to atherosclerosis or coro heart disease. Several years will be required before current investigations will yield an answer to this ques

Atromid-S® (clofibrate)

helps reduce elevated cholesterol and/or triglyceride levels — not just cholesterol alone



BRIEF SUMMARY

(For full prescribing information, see package circular.)

ATROMID-S® (clofibrate)

Antilipidemic agent for reduction of elevated serum lipids

INDICATIONS: ATROMID-S is indicated as adjunctive therapy to diet and other measures for the reduction of elevated serum cholesterol (especially the beta lipoprotein fraction) and/or triglycerides. Clofibrate appears to have a greater depressant effect on the very low density lipoproteins (S_f 20-400) rich in triglycerides than the low density lipoproteins (S_f 0-20) rich in cholesterol.

ATROMID-S is also indicated for treatment of patients with xanthoma tuberosum associated with hyperlipidemia. The skin lesions frequently regress with clofibrate.

It has not been established whether the drug-induced lowering of serum cholesterol or lipid levels has a detrimental, beneficial, or no effect on the morbidity or mortality due to atherosclerosis or coronary heart disease. Several years will be required before current investigations will yield an answer to this question.

CONTRAINDICATIONS: Clofibrate is contraindicated in pregnant women. While teratogenic studies have not demonstrated any effect attributable to clofibrate, it is known that serum of the rabbit fetus accumulates a higher concentration of clofibrate than that found in maternal serum, and it is possible that the fetus may not have developed the enzyme system required for the excretion of clofibrate.

It is contraindicated in lactating women since it is not known if clofibrate is secreted in the milk.

It is contraindicated in patients with clinically significant hepatic or renal dysfunction.

It is contraindicated in patients with primary biliary cirrhosis since it may raise the already elevated cholesterol in these cases.

WARNINGS: CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH ATROMID-S. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED USUALLY BY ONE-HALF (DEPENDING ON THE INDIVIDUAL CASE) TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS BEEN STABILIZED.

Strict birth control procedures must be exercised by women of childbearing potential. In patients who plan to become pregnant, clofibrate should be withdrawn several months before conception. Because of the possibility of pregnancy occurring despite birth control precautions in patients taking clofibrate, the possible benefits of the drug to the patient must be weighed against possible hazards to the fetus.

PRECAUTIONS: Before instituting therapy with clofibrate, attempts should be made to control serum lipids with appropriate dietary regimens, weight loss in obese patients, control of diabetes mellitus, etc.

Because of the long term administration of a drug of this nature, adequate base line studies should be performed to determine that the patient has significantly elevated serum lipid levels. Frequent determinations of serum lipids should be obtained during the first few months of ATROMID-S administration, and periodic determinations thereafter. The drug should be withdrawn after three months if response is inadequate. However, in the case of xanthoma tuberosum, the drug should be employed for longer periods (even up to one year) provided that there is a reduction in the size and/or number of the xanthomata.

Subsequent serum lipid determinations should be done to detect a paradoxical rise in serum cholesterol or triglyceride levels. Clofibrate will not alter the seasonal variations of serum cholesterol peak elevations in midwinter and late summer and decreases in fall and spring. If the drug is discontinued, the patient should be placed on an appropriate hypolipidemic diet, and his serum lipids should be monitored until stabilized, as a rise in these values to or above the original base line may occur.

During clofibrate therapy, frequent serum transaminase determinations and other liver function tests should be performed since the drug may produce abnormalities in these parameters. Hepatic biopsies are usually within normal limits. These effects are usually reversible when the drug is discontinued. If the hepatic function tests steadily rise or show excessive abnormalities, the drug should be withdrawn. Therefore use with caution in those patients with a past history of jaundice or hepatic disease.

Clofibrate may produce "flu like" symptoms (muscular aching, soreness cramping). The physician should differentiate this from actual viral and/or bacterial disease.

Use with caution in patients with peptic ulcer since reactivation has been reported. Whether this is drug-related is unknown.

The physician should monitor the patient with complete blood counts since peripheral anemia and, more frequently, leukopenia have been reported in patients who have been taking clofibrate. Whether these are drug-related is unknown.

Various cardiac arrhythmias have been reported with the use of clofibrate.

Several investigators have observed in their studies that clofibrate may produce a decrease in cholesterol linoleate but an increase in palmitoleate and oleate, the latter being considered atherogenic in experimental animals. The significance of this finding is unknown at this time.

ADVERSE REACTIONS: Of the pertinent reactions, the most common is nausea. Less frequently encountered gastrointestinal reactions are vomiting loose stools, dyspepsia, flatulence, and abdominal distress. Reactions reported less often than gastrointestinal ones are headache, dizziness, and fatigue; muscle cramping, aching, and weakness; skin rash, urticaria, and pruritus. There have been occasional cases of dry, brittle hair and of alopecia.

The following reported adverse reactions are listed alphabetically by systems:

Cardiovascular
- Cardiac arrhythmias
- Both swelling and phlebitis at site of xanthomas

Dermatologic
- Skin rash
- Alopecia
- Allergic reaction including urticaria
- Dry skin and dry brittle hair
- Pruritus

Gastrointestinal
- Nausea
- Diarrhea
- Gastrointestinal upset (bloating, flatulence, abdominal distress)
- Vomiting
- Stomatitis and gastritis

Genitourinary
- Impotence and decreased libido
- Findings consistent with renal dysfunction as evidenced by dysuria, hematuria, proteinuria, decreased urine output. One patient's renal biopsy suggested "allergic reaction."

Hematologic
- Leukopenia
- Potentiation of anticoagulant effect
- Anemia
- Eosinophilia

Musculoskeletal
- Myalgia (muscle cramping, aching, weakness)
- "Flu like" symptoms
- Arthralgia

Neurologic
- Fatigue, weakness, drowsiness
- Dizziness
- Headache

Miscellaneous
- Weight gain
- Polyphagia

Laboratory Findings
- Abnormal liver function tests as evidenced by increased transaminases (SGOT and SGPT), BSP retention, and increased thymol turbidity
- Proteinuria
- Increased creatine phosphokinase

Reported adverse reactions whose direct relationship with the drug has not been established: increased angina, peptic ulcer, gastrointestinal hemorrhage, rheumatoid arthritis, tremors, increased perspiration, systemic lupus erythematosus, blurred vision.

DOSAGE AND ADMINISTRATION: Adult Dose: The recommended dosage for adults is one capsule (500 mg.) four times daily.

In Children: Insufficient studies have been done in children to show safety and efficacy.

DRUG INTERACTIONS: Caution should be exercised when anticoagulants are given in conjunction with ATROMID-S (clofibrate). The dosage of the anticoagulant should be reduced usually by one-half (depending on the individual case) to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has been stabilized.

MANAGEMENT OF OVERDOSAGE: While there has been no reported case of overdosage, should it occur, symptomatic supportive measures should be taken.

HOW SUPPLIED: ATROMID-S—No. 243—Each capsule contains 500 mg. clofibrate, in bottles of 100.

Ayerst®
AYERST LABORATORIES
New York, N.Y. 10017

Let's face it. Conventional nitroglycerin is a notably unstable compound. It migrates from tablet to tablet, from tablet to cotton, from cotton to cap. Result: a wide variance in potency and therapeutic effect.

But with Nitrostat your angina patient gets a stabilized nitroglycerin. *Stabilized for uniform potency retention.* Thus, Nitrostat does the job that sublingual nitroglycerin is *supposed* to do. And does it *consistently*—providing the same pain-relieving potency, tablet after tablet. That's why more and more physicians are turning to Nitrostat.

Important facts to know whenever you're prescribing for a patient with a history of angina.

Nitrostat®
(nitroglycerin tablets, USP)
Sublingual Tablets
0.6 mg (1/100 gr)
0.4 mg (1/150 gr)
0.3 mg (1/200 gr)

Because the pain-relieving potency is locked inside–this nitroglycerin tablet will work like the next–and the next–and the next.

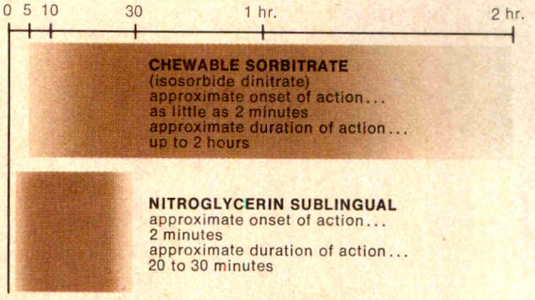
A walk without worry
Grandpa
has two hours
of angina protection.
CHEWABLE
SORBITRATE®
ISOSORBIDE DINITRATE 5MG.
goes beyond the
benefits of sublingual
nitroglycerin

For up to two hours of protection, your angina patient needs *more* than sublingual nitroglycerin. And Chewable Sorbitrate provides more.

☐ Acts almost as fast as nitroglycerin...lasts about 4 times as long.



☐ More stable in air than sublingual nitroglycerin: it can be stored or carried with no significant loss of potency.

☐ And when indicated: Sorbitrate® (isosorbide dinitrate) Sublingual 5 mg. and 2.5 mg.

SUMMARY OF PRESCRIBING INFORMATION

Mode of action: The mechanism of action of SORBITRATE (isosorbide dinitrate) is unknown, although the basic pharmacologic action is to relax smooth muscle. Isosorbide dinitrate reduces in number and severity the incidence of angina pectoris attacks, with concomitant reduction in nitroglycerin intake.

Indications: Sublingual and Chewable: For the prevention and treatment of angina pectoris.

Oral: For the relief of angina pectoris. It is not intended to abort the acute anginal episode. SORBITRATE WITH PHENOBARBITAL is indicated for patients in whom the angina pectoris is accompanied by anxiety or its related symptoms.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety. Phenobarbital may be habit forming.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: Route: Sublingual, oral and chewable tablets.

Individual Dose: To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg. Sublingually or orally, 5 to 10 mg. is the range commonly used although doses of up to 30 mg. have frequently been employed.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an anginal attack. Sublingual SORBITRATE may be taken p.r.n. or at 4 to 6 hour intervals; Oral SORBITRATE may be taken 3 to 4 times daily. CHEWABLE SORBITRATE may be taken for prompt relief of anginal pain 3 or 4 times daily. Although the onset and duration of effect of coronary nitrates may vary, following are the generally reported ranges of these values for SORBITRATE:

Onset of Effect: Sublingual and Chewable: 2 to 5 minutes. Oral: 15 to 30 minutes.

Duration of Effect: Sublingual and Chewable: 1 to 2 hours. Oral: Estimated to be 4 to 6 hours.

It is recommended that the oral dosage be taken on an empty stomach.

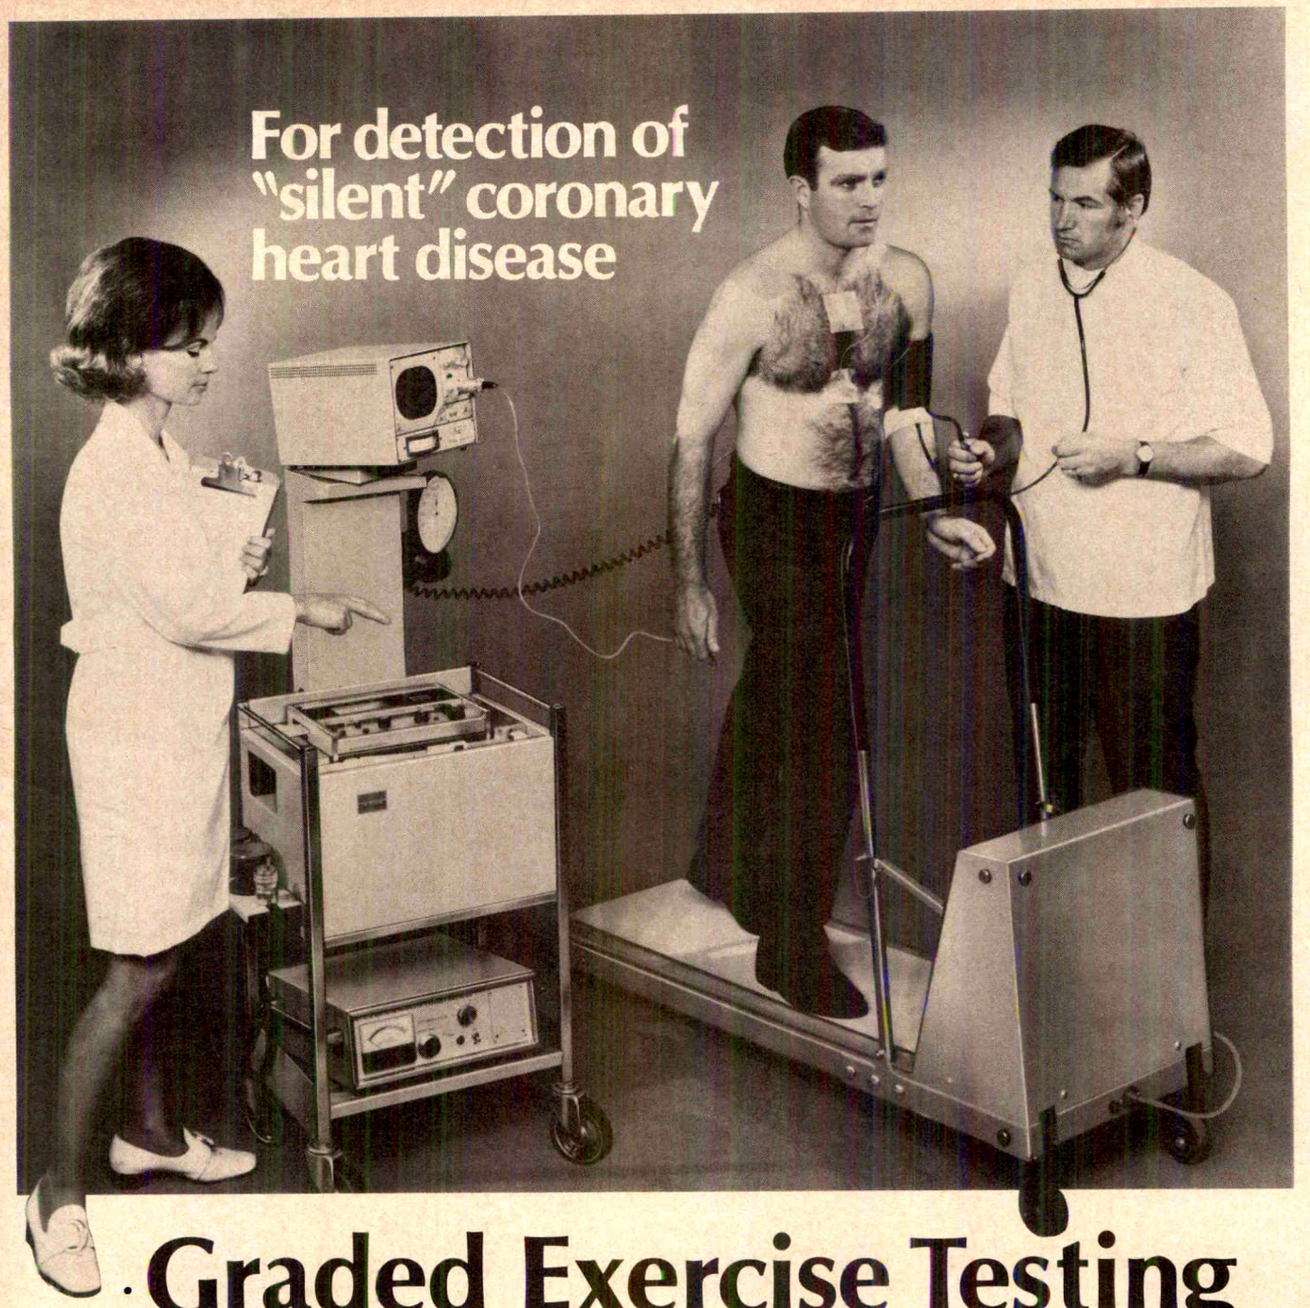
WILMINGTON, DEL. 19899



Graded Exercise Testing

The value and importance of treadmill stress-testing procedures lie in the detection of clinically unsuspected or "silent" coronary heart disease. By observing ECG responses to exercise tests, coronary disease can be detected prior to clinical manifestation in the form of angina pectoris or myocardial infarction.

Burdick's **Ex-ECG system** includes a 5″-screen cardiac monitor with integral HR-meter and 12-lead ECG preamp in combination with the **EK/5AS** automatic-start electrocardiograph and DC defibrillator—all conveniently mounted on a mobile console stand.

Versatility of the Burdick Ex-ECG system is further demonstrated by the fact the same equipment can also be utilized as an emergency cardiac station or a 1-bed ICU as needed.

Ask your Burdick dealer for a demonstration and complete information or write **The Burdick Corporation, Milton, Wisconsin 53563.**

The art of antianginal therapy

For centuries, treating the heart's ills has been the subtlest of arts. Even today, evaluating a drug for chronic angina pectoris involves the art of medicine as well as its science.

Persantine — over a decade of use

During more than a decade of clinical experience, compounding both science and art, Persantine has often been found useful in the long-term management of chronic angina pectoris.* It may:

eliminate or reduce the frequency of anginal attacks

improve exercise tolerance

reduce nitroglycerin requirements

Persantine — give enough — long enough

The recommended dosage: 50 mg. t.i.d. at least one hour before meals. *Give enough, long enough* — several weeks or longer of continuous therapy may be needed to see response.

Persantine®
Tablets of 25 mg.
dipyridamole

the non-nitrate
coronary vasodilator

Heart-Shaped Watermarks
14th to 16th Century, from C. M. Briquet "Les Filigrans," Leipzig, 1923.

It was believed during the middle ages that the earth was the center of the universe and the heart was the center of man; all other organs were inferior and grouped around it. The heart was believed to be the essence of man, his most essential and noble part. In art, the heart was depicted in a variety of symbols. These heart-shaped watermarks typify the symbology of the heart.

*INDICATIONS—Based on a review of this drug by the National Academy of Science-National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.

ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg. (2 tablets) three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

For complete details, please see the full prescribing information.

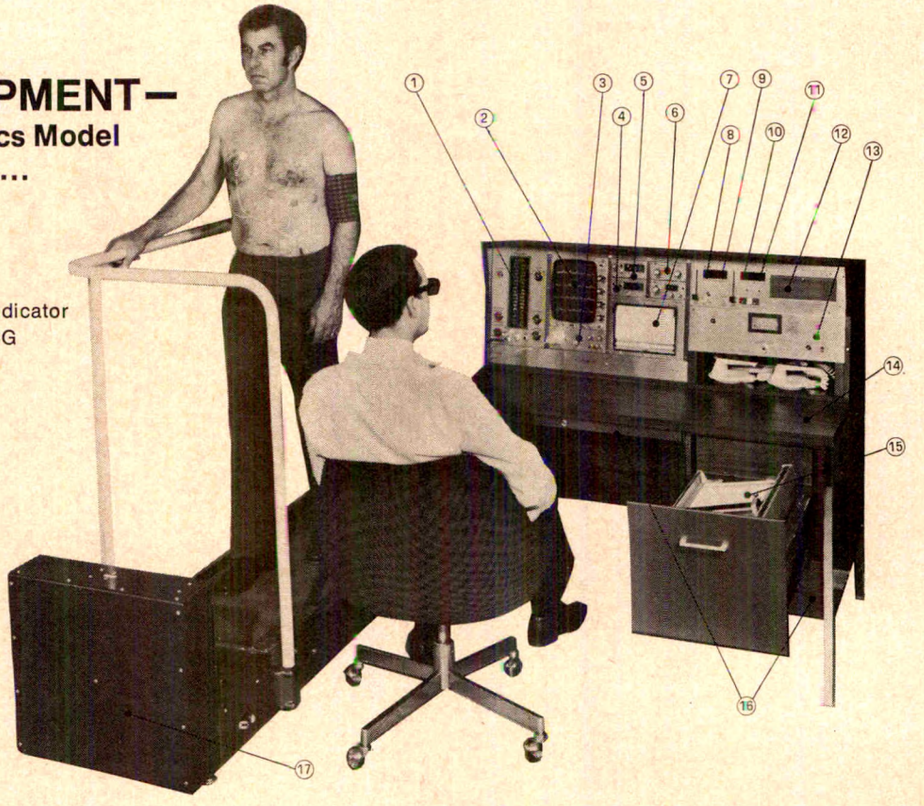
TWO GOOD REASONS WHY AVIONICS IS THE LEADER IN EXERCISE STRESS TESTING!

1. BETTER EQUIPMENT—

introducing the new Avionics Model 3600 ExerStress™ Console...

1. Automatic Blood Pressure Monitor
2. Four-Channel Memory Scope
3. Standard 12-lead Capability
4. Accurate Heart Rate Meter
5. ST-Segment Computer With PVC Indicator
6. Automatic Timer For Activating ECG Write-out
7. Three-Channel ECG Writer
8. Digital Display of Treadmill Speed
9. Digital Display of Treadmill Grade
10. Digital Elapsed Time Clock
11. Digital Display of Stage of Test
12. Automatic Programmer For Controlling Treadmill
13. DC Defibrillator
14. Work Area
15. XY Charter of ST-Segment, Heart Rate, and Time
16. Storage Areas
17. Treadmills: Finest Quality Available



2. BETTER SERVICE— full service and maintenance contracts available...

Compare the quality and performance of our system with all others. We'll bring the entire system, including the treadmill, to your hospital, clinic, or office and conduct an actual stress test under your control. You can prove the superior performance and diagnostic quality of our system to your own satisfaction.

Ask any competitor to bring and demonstrate his complete system to you, including treadmill exercising. If he refuses, that should tell you something! If you want the best, we've got it and we're ready to bring it to you.

SYMPOSIUM ON EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE

EZRA A. AMSTERDAM, JACK H. WILMORE and ANTHONY N. DeMARIA, *Guest Editors*

713 **Introduction**

715 **Methods of Exercise Testing. Step Test, Bicycle, Treadmill, Isometrics**

ROBERT A. BRUCE

This paper reviews the objectives, purposes, values and fine points of different methods currently used for exercise testing of cardiovascular function. The objectives of such studies should be to define functional aerobic capacity, the magnitude of its deviation from appropriate normal standards and the cardiovascular mechanisms of any impairment. These objectives can be met reliably with a multistage treadmill test. Clinical application of this test to identify persons at future risk for coronary artery disease is presented.

721 **Exercise Electrocardiography: Recognition of the Ischemic Response, False Positive and Negative Patterns**

ALBERT A. KATTUS

S–T segment depression in the left ventricular leads characteristic of ischemia may be obscured by conduction defects or falsely induced in patients taking digitalis or potassium-depleting drugs and in those with hypoadrenergic states, pectus excavatum or short P–R intervals. This paper discusses the significance of J point depression and the interpretation of false positive and false negative responses.

732 **Disturbances of Cardiac Rhythm and Conduction Induced by Exercise. Diagnostic, Prognostic and Therapeutic Implications**

ANTHONY N. DeMARIA, ZAKAUDDIN VERA, EZRA A. AMSTERDAM, DEAN T. MASON and RASHID A. MASSUMI

This paper review current knowledge of the electrophysiologic response of the heart to physical exertion and trends for future investigations. The presence of ventricular ectopic beats at rest does not preclude carefully performed graduated stress testing nor does their disappearance during effort exclude the presence of coronary artery disease. Ventricular premature beats that are frequent multifocal or repetitive or associated with light work loads are indicative of coronary artery disease involving two or more coronary vessels.

HEMODYNAMICS OF ANGINA PECTORIS* — PATIENTS RESTING AND EXERCISING, BEFORE AND AFTER ISORDIL® SUBLINGUAL
(isosorbide dinitrate)

BEFORE MEDICATION		AFTER 5 mg. ISORDIL SUBLINGUAL (isosorbide dinitrate)
	PULMONARY ARTERY (MEAN PRESSURE)		TOTAL PULMONARY RESISTANCE		CARDIAC INDEX		BRACHIAL ARTERY (MEAN PRESSURE)		TOTAL SYSTEMIC RESISTANCE	
IN ANGINA PECTORIS*

- to abort or terminate acute anginal attacks
- to reduce the frequency and severity of anginal episodes often caused by unavoidable everyday stress

ISORDIL® SUBLINGUAL
(ISOSORBIDE DINITRATE)

SUBLINGUAL TABLETS: 2.5 mg. and 5 mg.

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows:
"Probably" effective: When taken by the sublingual route, Isordil Sublingual is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

May we send you reprints, detailed information and/or professional samples?

CONTENTS

737 Indirect Assessment of Myocardial Oxygen Consumption in the Evaluation of Mechanisms and Therapy of Angina Pectoris

EZRA A. AMSTERDAM, JAMES L. HUGHES, III, ANTHONY N. DeMARIA, ROBERT ZELIS and DEAN T. MASON

Indirect assessment of myocardial oxygen consumption ($M\dot{V}O_2$) through derived indexes of heart rate and blood pressure, usually in the form of the product of heart rate × systolic blood pressure × systolic ejection period (triple product) or the product of the first two variables (double product), is useful for interpreting mechanisms and evaluating therapy of angina, but the technique must be applied cautiously because of the inherent limitations of these indirect indexes.

744 Experimental Observations on the Effects of Physical Training Upon Intrinsic Cardiac Physiology and Biochemistry

JAMES SCHEUER, SOMSONG PENPARGKUL and ASHOK K. BHAN

A moderate conditioning program of swimming in rats improved potential aerobic cardiac performance, producing increased capacity for coronary flow and oxygen delivery and higher levels of actomycin and myosin adenosine triphosphatase activity. Improved mechanisms of energy utilization confer partial resistance to hypoxia. Thus, hearts of conditioned rats converted chemical energy to external work more efficiently than hearts of sedentary rats.

752 Medical Screening of Patients with Coronary Artery Disease. Criteria for Entrance Into Exercise Conditioning Programs

MALCOLM M. McHENRY

This paper presents guidelines for patient safety and rejection in stress testing and training. Prospective participants in such exercise programs should be screened to assess motivation, eliminate undue risk and evaluate potential benefit. Patients with valvular heart disease, severe systemic hypertension and certain abnormal electrocardiographic patterns should be excluded.

757 Individual Exercise Prescription

JACK H. WILMORE

A successful exercise program must teach people why they should be physically active and motivate them to follow a personal activity program of endurance exercise (walk-jog-run, hiking, bicycling, swimming) at least three times weekly for 20 to 30 minutes at each session. The exercise prescription must pay attention to type of activity, frequency of participation and duration and intensity of exercise. The results from two programs using this approach show substantial improvement in the subjects' health profile.

760 Effects of Physical Training on Coronary Risk Factors

JOSEPH A. BONANNO and JAMES E. LIES

Data obtained in a 12 week, supervised physical training program for 20 exercising and 19 control subjects matched for age, occupation, coronary risk factors and physical fitness demonstrated significant improvement in physical fitness, systolic blood pressure and triglyceride levels in response to exercise, but not in cholesterol levels, smoking, obesity or psychological profile. Such a program is therapy of adjunctive value for subjects with hypertension or hypertriglyceridemia.

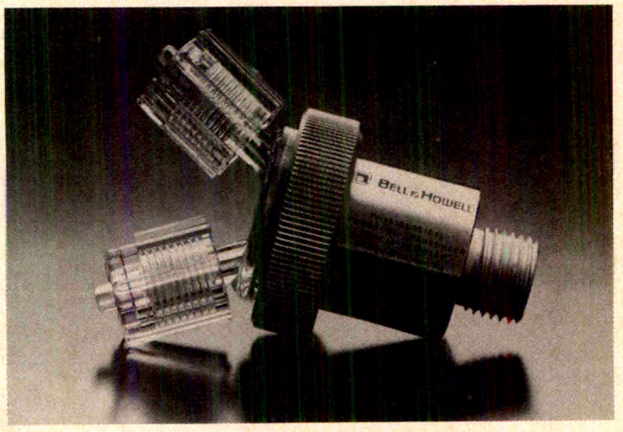
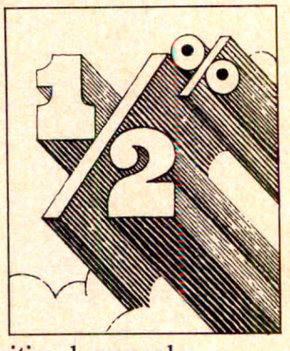
OUR BLOOD PRESSURE TRANSDUCER AND ITS CREDENTIALS.



The Bell & Howell Type 4-327 Physiological Blood Pressure Transducer Measures arterial and venous blood pressure. Specifically designed for use in hospital cath labs, ICUs and CCUs.

HOW ACCURATE? HOW GOOD?



It's the most accurate instrument available. *Twice* as accurate as any other make. Accurate down to ½ % as a matter of fact.

The Bell & Howell 4-327 transducer features a sensor design that has a four-active-arm Wheatstone bridge element with excellent calibration stability. Its advanced design includes a positive dome seal, stable output as saline fluid temperatures change, and a removable catch for quick interchangeability.

SPECIAL FEATURES:

Construction is rugged but its finish is that of a precision instrument. It has a positive seal using silicone rubber gaskets and is autoclaveable with/without connectors. Also, it has an overpressure stop to prevent damage up to 10 times the rated full scale pressure range and excellent frequency response for accurate monitoring of the heart pulse characteristic.

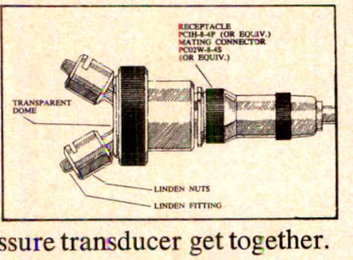
The Bell & Howell 4-327 is not affected by position. Not harmed by mechanical shock. And not shaken by vibration or microphonic transients. It's been a proven performer for 8 years.

THE PRESSURE IS ON US.

Our 4-327s are available on a moment's notice. We maintain an inventory which allows us to guarantee shipment within 24 hours of your order. That goes for new orders as well as repeat orders. New customers as well as old customers. Which means the world's most accurate blood pressure transducer is probably also the world's fastest, from our inventory into your hands.

Need service? Our delivery philosophy extends to our service policy. When you need us you can get us.

GET TOGETHER WITH THE 4-327.



Our transducers are our best representatives. But they can't answer a phone. However, if you call collect, (213) 796-9381 we'll see to it that you and our 4-327 blood pressure transducer get together.

WE'RE REWRITING THE BOOK.

It's true. We *are* rewriting the book the Bell & Howell Transducer Handbook. To be published soon, it will contain important information on the use of the 4-327. If you would like a preview of this information, send for your free copy of the 4-327 Instruction Manual. Write: Handbook Editor, Bell & Howell, CEC/Instruments Division, 360 Sierra Madre Villa, Pasadena, California 91109.

BELL & HOWELL

WE'RE REWRITING THE BOOK.

CONTENTS

765 **Long-Term Physiologic Adaptations to Exercise with Special Reference to Performance and Cardiorespiratory Function in Health and Disease**

WILLIAM C. ADAMS, MALCOLM M. McHENRY and EDMUND C. BERNAUER

After an excellent review of long-term physiologic adaptations of the cardiovascular system to exercise, this paper presents original data showing that after myocardial infarction most trained patients can achieve the performance levels of sedentary normal subjects except when residual disease causes myocardial dysfunction. Successful coronary artery bypass surgery rarely normalizes work performance and cardiorespiratory function although it may alleviate symptoms. Physical training in conjunction with bypass surgery improves work performance and aerobic power.

776 **Physical Activity After Myocardial Infarction**

WILLIAM L. HASKELL

Performance of physical activity by patients with uncomplicated myocardial infarction leads to earlier mobilization, reduced length of hospitalization, increased physical working capacity and more successful return to work. This article reviews the activity program in the coronary care unit, activity during the hospital stay, during convalescence and physical conditioning after recovery.

784 **Coronary Heart Disease as a Pediatric Problem. Prevention Through Behavior Modification**

JOHN L. BOYER

Alterations of behavior with emphasis on exercise of the endurance type and rational dietary habits are advocated for primary prevention of coronary heart disease in childhood. The beneficial effects of exercise may occur without alteration of coronary risk factors.

787 **Physical Fitness Programs for Adults**

KARL G. STOEDEFALKE

This paper explains the principles of exercise programs so that physicians can provide intelligent advice on this subject to their adult patients, especially those who want to do something about their "middle-age troika": weak musculature (especially of the abdomen), lack of flexibility and low endurance capability. Each adult should have a progressive exercise test before undertaking an exercise program.

END OF SYMPOSIUM

CLINICAL STUDIES

791 **Comparative Response to Isometric (Static) and Dynamic Exercise Tests in Coronary Disease**

JEAN-CLAUDE HAISSLY, ROGER MESSIN, SERGE DEGRE, POL VANDERMOTEN, BETTY DEMARET and HENRI DENOLIN

In 46 patients with arteriosclerotic heart disease the occurrence of S–T segment changes during isolated isometric exercise depended on the percent of maximal voluntary contraction applied but was less than during maximal dynamic exercise; angina seldom occurred. In 22 patients evidence of coronary insufficiency occurred more often during combined submaximal dynamic and isometric exercise than during isolated isometric exercise. The results suggest that isometric exercise tests are inadequate for diagnosing coronary insufficiency.

Laragh's HYPERTENSION MANUAL

Edited by John H. Laragh, M.D. of the College of Physicians and Surgeons, Columbia-Presbyterian in New York
A classic treatise for understanding, diagnosing and treating hypertension.
The most definitive work on the subject to date.

970 pages, 150 illustrations
Price: $37.00

The complete table of contents speaks for itself and is all the promotion that is needed.

Dr. Laragh's Hypertension Manual will undoubtedly become the standard reference work in Hypertension. Use the attached form to place your order. This is the first in a series of Yorke Medical Books—from the publishers of The American Journal of Cardiology, The American Journal of Medicine, The American Journal of Surgery, and Cutis.

LARAGH'S HYPERTENSION MANUAL/COMPLETE TABLE OF CONTENTS

PART I. CLINICAL AND EPIDEMIOLOGIC CHARACTERISTICS

■ Hypertension. Definitions, Natural Histories and Consequences
Sir George Pickering

■ Age, Race, Sex and Other Indices of Risk in Hypertension
Edward D. Freis

■ High Blood Pressure, Other Risk Factors and Longevity: The Insurance Viewpoint
Edward A. Lew

■ Renin as a Risk Factor in Essential Hypertension: More Evidence
Hans R. Brunner, Jean E. Sealey and John H. Laragh

■ Searching Out Low Renin Patients: Limitations of Some Commonly Used Methods
Jean E. Sealey and John H. Laragh

PART II. MECHANISMS

■ Arterial Pressure Regulation. Overriding Dominance of the Kidneys in Long-Term Regulation and in Hypertension
Arthur C. Guyton, Thomas G. Coleman, Allen W. Cowley, Jr., Konrad W. Scheel, R. Davis Manning, Jr. and Roger A. Norman, Jr.

■ A Viewpoint Concerning the Enigma of Hypertension
Louis Tobian, Jr.

■ The Control of Renin Release
James O. Davis

■ The Control of Aldosterone Secretion in Normal and Hypertensive Man: Abnormal Renin-Aldosterone Patterns in Low Renin Hypertension
John H. Laragh, Jean E. Sealey and Hans R. Brunner

■ Physiologic Characteristics of Hypertension
Harriet P. Dustan, Robert C. Tarazi and Emmanuel L. Bravo

■ Blood Pressure and Cardiac Performance
Jay N. Cohn

■ Neurogenic Factors in Human Hypertension: Mechanism or Myth?
Vincent DeQuattro and Yukio Miura

■ The Renin-Angiotensin-Aldosterone System in Pathogenesis and Management of Hypertensive Vascular Diseases
John H. Laragh, Leslie Baer, Hans R. Brunner, Fritz R. Bühler, Jean E. Sealey and E. Darracott Vaughan, Jr.

■ Plasma Aldosterone-Renin Interrelationships in Various Forms of Essential Hypertension. Studies Using a Rapid Assay of Plasma Aldosterone
Fritz R. Bühler, John H. Laragh, Jean E. Sealey and Hans R. Brunner

■ Renin, Angiotensin and Hypertensive Vascular Damage: A Review
Jorn Giese

■ Diabetes and Hypertensive Vascular Disease: Mechanisms and Treatment
A. Richard Christlieb

■ Toxemia of Pregnancy: Mechanism and Therapeutic Management
Leon Speroff

■ Adrenal Mineralocorticoid Hormones Causing Hypertension
E. G. Biglieri, J. R. Stockigt and M. Schambelan

■ Hypertension in Chronic Renal Failure. An Abnormal Relation Between Sodium and the Renin-Angiotensin System
M. A. Schalekamp, D. G. Beevers, J. D. Briggs, J. J. Brown, D. L. Davies, R. Fraser, M. Lebel, A. F. Lever, A. Medina, J. J. Morton, J. I. S. Robertson and M. Tree

■ Renovascular Hypertension. Mechanisms, Natural History and Treatment
James C. Hunt and Cameron G. Strong

■ The Physiology of Renin Secretion in Essential Hypertension. Estimation of Renin Secretion Rate and Renal Plasma Flow from Peripheral and Renal Vein Renin Levels
Jean E. Sealey, Fritz R. Bühler, John H. Laragh and E. Darracott Vaughan, Jr.

■ Renovascular Hypertension: Renin Measurements to Indicate Hypersecretion and Contralateral Suppression, Estimate Renal Plasma Flow and Score for Surgical Curability
E. D. Vaughan, Jr., F. R. Bühler, J. H. Laragh, J. E. Sealey, L. Baer and R. H. Bard

PART III. METHODS

■ An Evaluation of Measurement Performance of Selected Blood Pressure Devices
Darwin R. Labarthe, C. Morton Hawkins and Richard D. Remington

■ Assay of Plasma Catecholamines. An Approach to Evaluating Altered Sympathetic Activity in Essential Hypertension
Karl Engelman

■ The Measurement of Plasma Renin Activity in Man
Jean E. Sealey, John H. Laragh, Joan Gerten-Banes and Rose M. Aceto

■ Measurement of Urinary Aldosterone Excretion in Man
Jean E. Sealey and John H. Laragh

■ Radioimmunoassay of Plasma Aldosterone
Fritz R. Bühler, Jean E. Sealey and John H. Laragh

PART IV. MANAGEMENT

■ Evaluation and Care of the Hypertensive Patient
John H. Laragh

■ Standards for the Quality Care of Hypertensive Patients in Office and Hospital Practice
Carlos R. Ayers, Arthur R. Slaughter, Harvey D. Smallwood, Frank E. Taylor and Richard E. Weitzman

■ Hypertension—A Community Problem
Joseph A. Wilber and J. Gordon Barrow

■ The Treatment of Hypertension. Why, When and How
Edward D. Freis

■ Correlation of Pathophysiology and Pharmacotherapy in Primary Hypertension
Jan Koch-Weser

■ Management of Severe Hypertension
Priscilla Kincaid-Smith

■ Hypertensive Emergencies
Frank A. Finnerty, Jr.

PART V. RENIN SYSTEM IN TREATMENT STRATEGY

■ Vasoconstriction-Volume Analysis for Understanding and Treating Hypertension. The Use of Renin and Aldosterone Profiles
John H. Laragh

■ The Volume Factor in Low and Normal Renin Essential Hypertension. Its Treatment with Either Spironolactone or Chlorthalidone

797 Comparison of the Two-Step and Maximal Exercise Tests in Patients with Coronary Artery Disease

PAUL SCHWEITZER, V. MICHAEL JELINEK, MICHAEL V. HERMAN and RICHARD GORLIN

In 10 men with a chest pain syndrome who underwent the two-step test, maximal exercise test and coronary angiography during the same admission, neither the two-step test nor the maximal exercise test greatly helped to diagnose coronary artery disease in the patients with single vessel disease. Both exercise tests proved more sensitive in patients with multivessel disease. In certain patients the effects of augmented venous return in the supine position in increasing cardiac mechanical activity through the Starling effect may be as important a factor in eliciting ischemia as the achieved heart rate.

801 Arm-Crank Ergometry: A New Method for the Evaluation of Coronary Artery Disease

DAVID J. SHAW, MICHAEL H. CRAWFORD, JOEL S. KARLINER, GEORGE DiDONNA, RICHARD M. CARLETON, JOHN ROSS, Jr. and ROBERT A. O'ROURKE

Using a modified bicycle ergometer as an arm-crank device, these investigators conclude that arm-crank exercise is comparable to treadmill exercise and a reliable alternative method for evaluating suspected coronary artery disease in patients unable to perform leg exercise. This conclusion is based on effects on heart rate, blood pressure and S–T segment in 46 patients.

806 Effects of Perhexiline on Symptomatic and Hemodynamic Responses to Exercise in Patients with Angina Pectoris

CARL J. PEPINE, STEVEN J. SCHANG and CARL R. BEMILLER

Perhexiline given orally to 16 patients with coronary artery disease and angina pectoris favorably influenced their clinical and hemodynamic responses to exercise. This drug prevented effort-induced angina, reduced exercise tachycardia, prolonged diastolic pressure-time interval and reduced ischemia-related left ventricular dysfunction. This beneficial effect, lasting 4 hours, is attributed to enhanced myocardial oxygen delivery.

813 Myocardial Infarction After Exercise-Induced Electrocardiographic Changes in a Patient with Variant Angina Pectoris

R. LELDON SWEET and L. THOMAS SHEFFIELD

Ten minutes after a multiple stop stress test during which he achieved a maximal heart rate of 120 beats/min without symptoms this 61 year old postmaster with variant angina pectoris had an acute anterolateral wall myocardial infarction. The resting ST–T abnormality became normal during exercise. Since patients with variant angina pectoris may be particularly high risk subjects for maximal or submaximal stress testing. The use of continuous Holter monitoring may prove more physiologic and less hazardous to demonstrate the typical S–T changes during chest pain episodes.

Symposium on Exercise in Cardiovascular Health and Disease

EZRA A. AMSTERDAM, MD, FACC, JACK H. WILMORE, PhD and ANTHONY N. DeMARIA, MD, *Guest Editors*

Introduction

Scientific interest in exercise as a means of disrupting man's biological homeostasis has existed for many centuries. It was not until relatively recently, however, that concerted efforts were made to gain insight into man's functional adaptability to the stress of exercise. With the establishment of the Harvard Fatigue Laboratory in 1927, a group of dedicated scientists began the systematic exploration of this major area of physiologic interest.[1] Although the Harvard Fatigue Laboratory was short-lived, continuing only until 1947, its pioneering efforts into the physiology of exercise provided the foundation for much of our present knowledge and investigation of this subject. The current application of exercise to the treatment of cardiovascular disease is but one extension of this early work. Since the introduction more than 4 decades ago[2] of systematic analysis of the circulatory response to exercise as a means of investigating cardiovasuclar status, followed by its application to the detection of latent myocardial ischemia,[3] exercise has played an increasingly important role in the diagnosis and functional evaluation of cardiac disease and, more recently, in its treatment and prevention.[4]

In recognition of the widespread interest in, and expanding application of, exercise in cardiovascular health and disease, an integrated, multidisciplinary examination of current concepts in this broad field was undertaken in the form of a conference presented by the American College of Cardiology and the University of California, Davis, School of Medicine in December 1972. This conference, "Exercise and the Heart," brought together clinicians, exercise physiologists, physical educators, epidemiologists and laboratory scientists to facilitate better understanding of exercise and its role in cardiovascular health and disease and thereby promote its more rational application in the normal population as well as in patients with cardiovascular disorders.

The proceedings at Davis have been formalized in this Symposium. The presentations divide naturally into three groups. The first four papers deal with the use and interpretation of exercise stress testing in the evaluation of cardiac disease. The second section is concerned with the effects of exercise training at experimental and clinical levels. The alterations in cardiac physiology and metabolism associated with training are explored, and the effects of conditioning on clinical cardiac disease are examined. The third group of papers is concerned with the design of effective training programs conducive to participation and adherence by appropriate subjects.

In the first paper, Bruce describes exercise testing in terms of indications, methods and respective physiologic types. His discussion focuses on assessment and clinical implications of functional aerobic impairment and electrocardiographic S–T segment changes. In the next study, Kattus addresses himself to the frequent and important clinical problem posed by interpretation of S–T segment abnormalities in evaluating the presence of myocardial ischemia. DeMaria et al. then discuss arrhythmias and conduction defects occurring during exercise stress testing and review current knowledge regarding the diagnostic, prognostic and therapeutic implications of these electrophysiologic events. The authors note that exercise may be associated with both provocation and, by overdrive suppression, abolition of ventricular arrhythmias present at rest or associated with low levels of exercise. They emphasize that the response of ventricular ectopic beats to exertion does not reliably discriminate between normal persons and patients with cardiac disease. Amsterdam et al. consider the use of exercise testing to determine the severity of

angina. They emphasize the distinction between external work, performed by the skeletal muscles, and internal work or cardiac performance. The latter is critical to assessment of angina and can be conveniently evaluated by use of indirect hemodynamic indexes of myocardial oxygen consumption such as heart rate-blood pressure product. Within the limits of this method, which are stressed, meaningful evaluation of the mechanisms and therapy of angina can be achieved.

Scheuer et al., initiating the papers on the effects of training, provide experimental evidence of enhanced functional performance and a protective effect against hypoxic stress in association with favorable alterations in myocardial contractile proteins in hearts from trained animals as opposed to controls. The succeeding studies in this group deal with clinical application of the potential benefits of exercise training. McHenry indicates that selection of subjects for training programs entails systematic evaluation to eliminate patients at excessive risk, assess motivation and determine the individual's potential for benefit from training. Wilmore, in his discussion of the exercise prescription, directs attention to the individualization of the exercise regimen consistent with the derivation of maximal benefits. He notes that endurance activity for at least 20 to 30 minutes 3 times weekly at a target heart rate 75 percent of that associated with maximal oxygen consumption renders a significant training effect on cardiovascular functional parameters. Bonanno and Lies then evaluate the effect of such an exercise program upon coronary risk factors in clinically normal men. They demonstrate significant decreases in systolic blood pressure of hypertensive subjects and in serum triglycerides of all participants in the training program. Adams and co-workers describe their experience with exercise training in normal middle-aged men and patients who have had a myocardial infarction or aortocoronary bypass surgery. They present data to illustrate the values and limitations of a training program for these patients. Haskell considers the broad topic of physical activity at all stages in the patient who has had a myocardial infarction. He emphasizes that a training program should begin with early ambulation during the hospital phase of the illness. Such gradually progressive activity minimizes the adverse cardiovascular and psychological effects of prolonged bed rest. Regular subsequent activity based upon a carefully determined exercise prescription is associated with increased maximal oxygen consumption and work capacity.

Boyer, discussing implementation of effective training programs, the subject of the third section, emphasizes that prevention of coronary heart disease should begin in childhood. Thus, not only should early elimination of risk factors be rigorously pursued, but also adherence to patterns of exercise of the endurance type should be established in the formative years. Stoedefalke concludes the Symposium with a balanced exposition of the requisite features of a successful adult physical fitness program in which he stresses the importance of an imaginatively and individually tailored training regimen, designed and supervised by an individual well versed in the theory and practice of exercise testing.

Methods of Exercise Testing

Step Test, Bicycle, Treadmill, Isometrics

ROBERT A. BRUCE, MD, FACC

Seattle, Washington

Methods of exercise testing are considered in relation to physiologic types, clinical applications and objectives, physiologic differences in end points and inferences, and comparison of oxygen requirements and circulatory responses. Hazards and safety precautions are cited.

The multistage treadmill test of submaximal and maximal exercise is described in terms of oxygen requirements, measurement of maximal oxygen uptake, approach to maximal uptake, determination of functional aerobic impairment and assessment of circulatory and electrocardiographic responses. Initial findings are presented of a new, prospective community study ("Seattle Heart Watch") designed to test the hypothesis that specific persons at risk for future angina pectoris, myocardial infarction or sudden death can be identified by this method.

Appraisal of exercise testing methods properly requires consideration of physiologic types of exercise, clinical applications and objectives, physiologic differences between major classes of dynamic tests, comparison of oxygen requirements and circulatory responses, recommended objectives and rationale, experience with general application and clinical evaluation of therapeutic intervention.

Physiologic Types of Muscular Exercise and Circulatory Implications

Basically, there are three types of skeletal-muscle contractions. The first type is dynamic with rhythmical contractions of extensor and flexor muscle groups. Examples of dynamic exercise include walking, stepping, pedaling, jogging and running. The alternating contractions of these muscle groups facilitate arterial inflow to the working muscles and venous return to the right heart chambers. The second type is isometric, or sustained muscle contraction. Examples of isometric exercise include handgrip, isometric weight-lifting and water-skiing. These sustained contractions limit arterial inflow by compressing small arteries and do not facilitate venous return. The third type represents the combination of the first two. Examples of this type of exercise include carrying a heavy load while walking or executing vigorous handgrips while pedaling a bicycle.

Dynamic vs. isometric exercise: Of the two major physiologic types of exercise stress, dynamic exercise is clearly preferred because the circulatory responses are directly proportional to relative aerobic requirements. In a comparative study of the two types of exercise in the same four normal subjects, blood pressure responses were exaggerated with isometric exertion (Fig. 1) and heart rate responses were greater with dynamic exercise (Fig. 2).[1] Even when each type of exertion was repeated after inadequate time for recovery, there was no significant change in these patterns. Accordingly, isometric exertion, especially if performed at a level more than 25 percent of maximal voluntary contraction, can be hazardous because the acute increases

in blood pressure are greatly in excess of aerobic requirements[2] (Table I). Anecdotal data indicate hazards of acute pulmonary edema, arrhythmias, myocardial infarction and even sudden death (two instances during water-skiing) in patients with heart disease. Whatever type of stress test is used, it is important not to limit observations to electrocardiographic changes of possible myocardial ischemia of diagnostic significance, but also to note changes in rhythm, heart rate and blood pressure as indicators of circulatory impairment.

Physiologic Differences Between Major Types of Conventional Tests of Dynamic Exercise

Conventional tests of dynamic exercise can be subdivided into two major categories with important pathophysiologic differences.

Submaximal tests: These may be single stage or multistage, with continuous or discontinuous work loads and *predetermined, arbitrary* end points. These end points may be the number of trips on

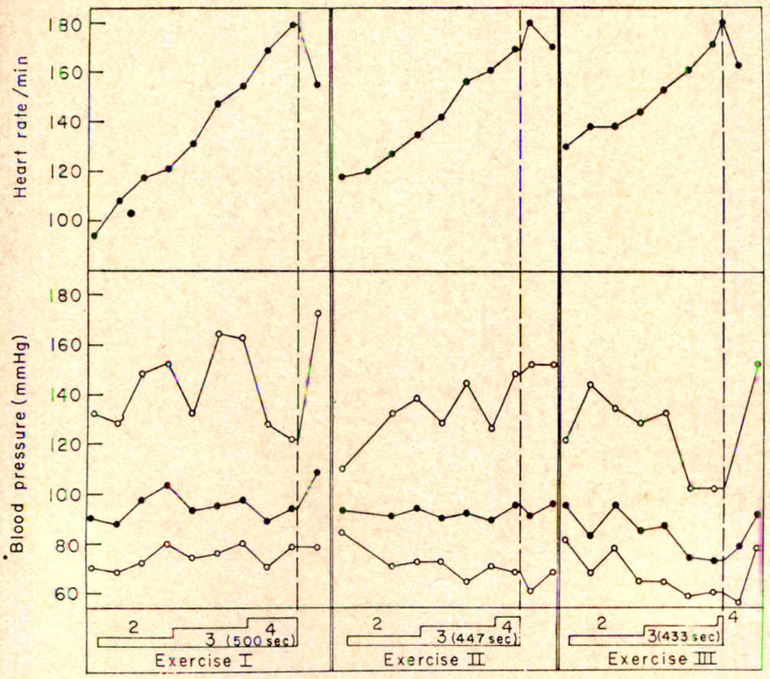

FIGURE 2. Heart rate and blood pressure responses to multistage treadmill test of dynamic exercise to maximal limits in the same four normal subjects. Again note reproducibility on repetition after only 10 minutes **(center panel)** and only 3 minutes **(right panel)** of recovery. (Reprinted by permission from Bruce et al.[1])

TABLE I

Circulatory Responses to Voluntary Handgrip, 30 Percent of Maximal, Held to Limit of Fatigue

	At Rest	Peak Response		% Change
Cutaneous circulation	Normal	Intensely hyperemic		...
Blood pressure (mm Hg)	112/82	206/142	(+94/+60)	83/73
Heart rate (beats/min)	77	92	(+15)	19

standardized steps (even when adjusted for sex, age and weight), work load, oxygen requirement or, more commonly, a target heart rate based upon a percentage of estimated maximal heart rate. The latter is obtained from age and activity status then compared with average values of "normal" persons. All these criteria fail to consider that maximal heart rate is distinctly lower in patients with heart disease, especially those with myocardial ischemia, and that the range of normal responses clearly documented by the 95 percent confidence intervals is fairly broad. Furthermore, when one of these arbitrary end points is attained, it is necessary to rely upon the subjective assessment of the patient to determine whether that arbitrary level of activity represents a low, intermediate or high fraction of his capacity. Accordingly, exercise capacity is poorly defined and, consequently, reserve function is uncertain. The majority of submaximal test procedures take into consideration that their arbitrary limits exceed the capabilities of the more impaired patient and include a variety of other indications for stopping stress, some of which may be ambiguous.

Maximal tests: Individualized, self-determined symptomatic end points of *maximal possible performances* permit each subject to attain his physiologic limit while the various symptoms, signs and circulatory, electrocardiographic and metabolic responses are observed and recorded. With a multistage treadmill protocol, this procedure has been feasible in more than 97 percent of more than 15,000 tests in our experience. These end points are more reproducible than the responses at any submaximal work load. Furthermore, with this protocol, maximal oxygen uptake and its relation to expected normal values (adjusted for sex, age and activity status) can be readily defined from elapsed time in minutes and a nomogram.

Comparison of Oxygen Requirements and Circulatory Responses

Oxygen requirements of five different submaximal exercise tests, defined by measurements in the same normal subjects, are shown in Figure 3. The greatest energy expenditure in these five tests occurred with the double Master two-step test, which required 23

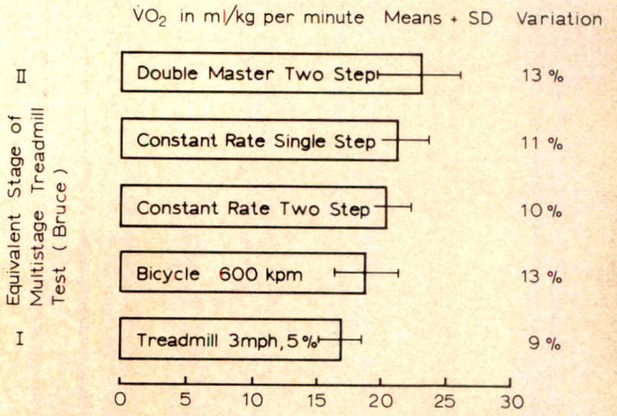

FIGURE 3. Aerobic costs of five commonly used submaximal tests. (Adapted by permission from Blackburn et al.[3]) $\dot{V}O_2max$ = maximal oxygen uptake.

ml/kg body weight per min.[3] Results of this test also exhibited the greatest variability in the relation of standard deviation to the means. The least variable, and therefore most reproducible, results were found at a low level of energy expenditure on the treadmill.

Peak oxygen uptake: Maximal tests should define the peak oxygen uptake, but when the same men are tested by different methods to a level of maximal exertion, values for oxygen uptake differ (Fig. 4). The lowest value was obtained with the bicycle ergometer, and the highest with a multistage treadmill.[5] Other studies of patients with coronary artery disease[6] indicate that ventilation as well as heart rate, arterial pressure, pressure-rate product and systemic resistance are greater in the same patients during bicycle exercise than during treadmill testing.[6] These differences are attributed to more vigorous muscle contractions with the ergometer, particularly in persons not conditioned to bicycling.

Maximal oxygen uptake ($\dot{V}O_2max$): When a multistage treadmill test of maximal exercise is used, and the subject continues exertion until a self-determined end point of fatigue or other limiting symptoms, it is remarkable that the approach to maximum

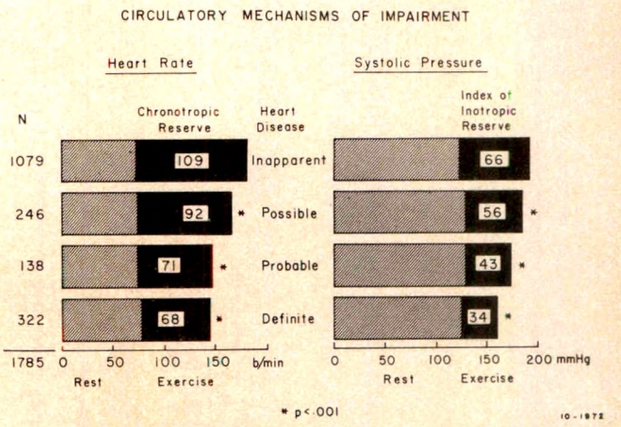

FIGURE 10. Circulatory mechanisms of impairment in thesame 1 men.

appears similar in all ambulatory persons (provided that subjects do not use the handrails for partial support of body weight).[7,8] (Fig. 5). This applies even though there are striking differences in weight-adjusted $\dot{V}O_2$max. Thus, at 1 or 2 minutes before $\dot{V}O_2$max the average percent $\dot{V}O_2$max is similar for normal subjects and patients with heart disease. For the one in five subjects who continue for 1/2 to 1 minute beyond the point of $\dot{V}O_2$max by greater utilization of anaerobic glycolysis for the source of additional energy, $\dot{V}O_2$max is reduced about 3 to 5 percent. Recent unpublished observations of ours indicate that this reduction is due to a further decrease in stroke volume rather than to reductions in either heart rate or arteriovenous oxygen difference.

$\dot{V}O_2$max in liters per minute normally is greater in men than in women (Fig. 6). Accordingly, the relative aerobic costs for a given submaximal exertion are greater in women than in men; they are still greater in men with cardiac disease than in either normal men or normal women, because the weight-adjusted value of $\dot{V}O_2$max is even lower in patients with cardiac disease.

$\dot{V}O_2$max can be increased acutely with nitroglycerin in patients with coronary artery disease but not in normal subjects[9] (Fig. 7). Thus, in the presence of myocardial ischemia, work capacity is enhanced transiently when the preload and afterload imposed on the ischemic myocardium are reduced by peripheral vasodilatation; then the available coronary flow of oxygenated blood is more nearly adequate for the reduced hemodynamic stress applied.

Oxygen costs of isometric work, even when forced to maximal limits, do not approach the values obtained with dynamic exercise. Thus, isometric exertion is useless for testing functional aerobic capacity and does not confer the benefits of endurance training obtained by dynamic exercise conditioning.

Recommended Objectives and Rationale of Testing

The goals of exercise testing should not be restricted to electrocardiographic observations of myocardial ischemia as possible evidence of coronary vascular disease. Instead, the objectives should be to define functional aerobic capacity, the magnitude of its deviation from appropriate normal standards, and the cardiovascular mechanisms of any impairment.

These objectives can be met rapidly, reliably and safely with a multistage treadmill test that encompasses submaximal and maximal exercise.[6] The oxygen requirements for the first four stages or 12 minutes are shown in Figure 8, and average values for maximal oxygen uptake are shown in Figure 6. In meeting these requirements, it is important that none of the body weight be supported by leaning on the handrails; this reduces oxygen requirement and increases variability of measurements of both intensity and duration. In our setting, each subject undergoes a medical examination and a resting electrocardiogram to detect contraindications before testing, and the patient and the electrocardiogram are monitored during and immediately after testing. As a result of these precautions we have observed a morbidity rate of less than 0.1 percent and no mortality in more than 15,000 tests. This experience compares favorably with that of the national experience surveyed by Rockmis and Blackburn,[10] who reported respective morbidity and mortality rates of 2.4 and 1 per 10,000 tests, in a survey of 170,000 exercise tests. Despite these precautions we have witnessed three myocardial infarctions; the first occurred in a clinically normal subject who became acutely ill while taking a hot shower after exercise testing.[11] There also have been three instances of cardiac arrest; in all three, defibrillation was quickly accomplished and myocardial infarction did not occur. Thus, the risk, even to patients with coronary artery disease, is far less than that of coronary arteriography.

With this protocol, $\dot{V}O_2$max and functional aerobic impairment can be derived by regression equations or nomogram from the total duration of exercise.

Clinical Application of Maximal (Treadmill) Exercise Testing

In July 1971, a prospective study of exercise testing was initiated in 15 testing sites in the Seattle area. These included four hospital laboratories, the medi-

cal department in a major industry, and 10 private clinics and offices of physicians and cardiologists. The objectives were to test the hypothesis that persons at risk could be detected earlier and more frequently by maximal exercise testing, and that the mechanisms of clinical events might be predicted in terms of angina or infarction resulting from ischemia, or sudden death from arrhythmia. In the first 16 months, more than 2,200 persons have been tested with only three complications and no mortality.[12] Analysis of the first 1,785 men reveals interesting findings in relation to 1,079 normal subjects and 706 patients classified as having "inapparent" versus "possible," "probable" or "definite" coronary heart disease (Fig. 9). Among the normal subjects, $\dot{V}O_2max$ estimated from the duration of multistage exercise with this treadmill protocol averaged 37 ml/min or 99 percent of expected normal. Accordingly, functional aerobic impairment of only 1 percent represented remarkable validation of the nomographic technique for assessment of functional aerobic capacity. Functional aerobic impairment increased with clinical severity of disease from 12 to 47 percent. Furthermore, determination of the changes in heart rate from the electrocardiogram and changes in systolic blood pressure by sphygmomanometry provided significant insights into the circulatory mechanisms of impairment (Fig. 10). The rate changes averaged 109 beats/min in normal subjects and fell progressively to 92, 71 and 68 beats/min as severity of disease increased. The pressure changes averaged 66 mm Hg in normal subjects and fell with increasing severity of disease to 56, 43 and 34 mm Hg. The former represents the chronotropic reserve, and the latter an index of inotropic reserve of the left ventricle. Actually, since peripheral vascular resistance diminishes markedly with maximal exercise, the change in pressure underestimates the inotropic reserve of the ventricle.

In conclusion, some of the salient principles of exercise testing of ambulatory normal subjects and patients with heart disease have been reviewed briefly. Isometric exercise may be hazardous; dynamic exercise offers greater benefits and fewer risks. Experience with the multistage treadmill test indicates that it is a practical, reliable and safe method of testing, with the distinct advantage that its use permits definition of the functional capacity of the cardiovascular system.

Exercise Electrocardiography: Recognition of the Ischemic Response, False Positive and Negative Patterns

ALBERT A. KATTUS, MD

Los Angeles, California

The ischemic electrocardiographic response is characterized by S–T segment depression in the left ventricular leads. When this response is elicited by exercise and is accompanied by anginal discomfort, it constitutes powerful diagnostic evidence of the presence of coronary arterial obstructive disease. The amount of exercise required to elicit the response is closely related to the extent of the obstruction. S–T segment elevation provoked by exercise rarely occurs with proximal severe stenosis in the left anterior descending coronary artery or in leads exploring the region of healed myocardial infarcts. Depression of the J point may be an ischemic manifestation reversible by administration of nitroglycerin.

The ischemic electrocardiographic response may be obscured by conduction defects as in bundle branch block and healed myocardial infarcts. False positive ischemic responses may be encountered in patients taking digitalis glycosides or potassium-depleting drugs, or in patients with hyperadrenergic states, pectus excavatum or short P–R intervals.

Depression of the S–T segment has been recognized as the electrocardiographic hallmark of myocardial ischemia since Feil and Segal[1] recognized its association with angina pectoris in their classic observations published in 1928. They observed a man with a normal resting electrocardiogram who had a spontaneous attack of angina while an electrocardiogram was being taken. The tracing they recorded resembled that of Figure 1, which represents the sequential electrocardiographic changes seen in one of our patients who experienced an anginal attack, probably attributable to anxiety, as the tracing was being recorded. Depression of the S–T segment with a horizontal configuration coincided with the development of anginal pain similar to the pain he customarily had during physical exertion. Relief of pain after sublingual administration of nitroglycerin was associated with return of the S–T segment to the base line. This sequence of events with the association of angina and depressed S–T segment, both reversed by the administration of nitroglycerin, constitutes very strong evidence, perhaps even proof, that the S–T segment depression was due to myocardial ischemia.

The impracticality of obtaining electrocardiographic monitoring of naturally occurring anginal attacks has led to the development of provocative tests among which the two-step test of Master[2] is the only one to have survived into the present era. This test, considered a single stage test since the work load remains constant throughout the duration of the exercise period, has been supplanted in our institution in recent years by a multistage treadmill exercise test.[3] The idea underlying multistage testing is that one can begin by subjecting a patient to a low level of work load not in excess of what he is customarily able to do without distress. The work load can then be increased in small increments during continuous electrocardiographic monitor-

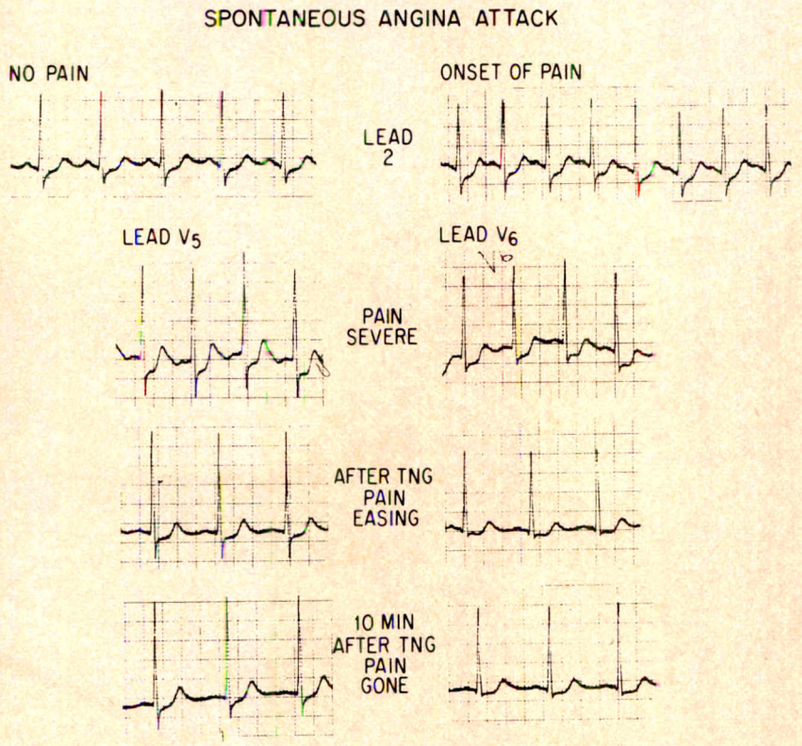

FIGURE 1. Electrocardiograms recorded during development of a spontaneous anginal attack and during its relief by administration of sublingual nitroglycerin (TNG). The fully developed ischemic response of horizontal depression of S–T segments is seen during the height of the attack in lead V_6.

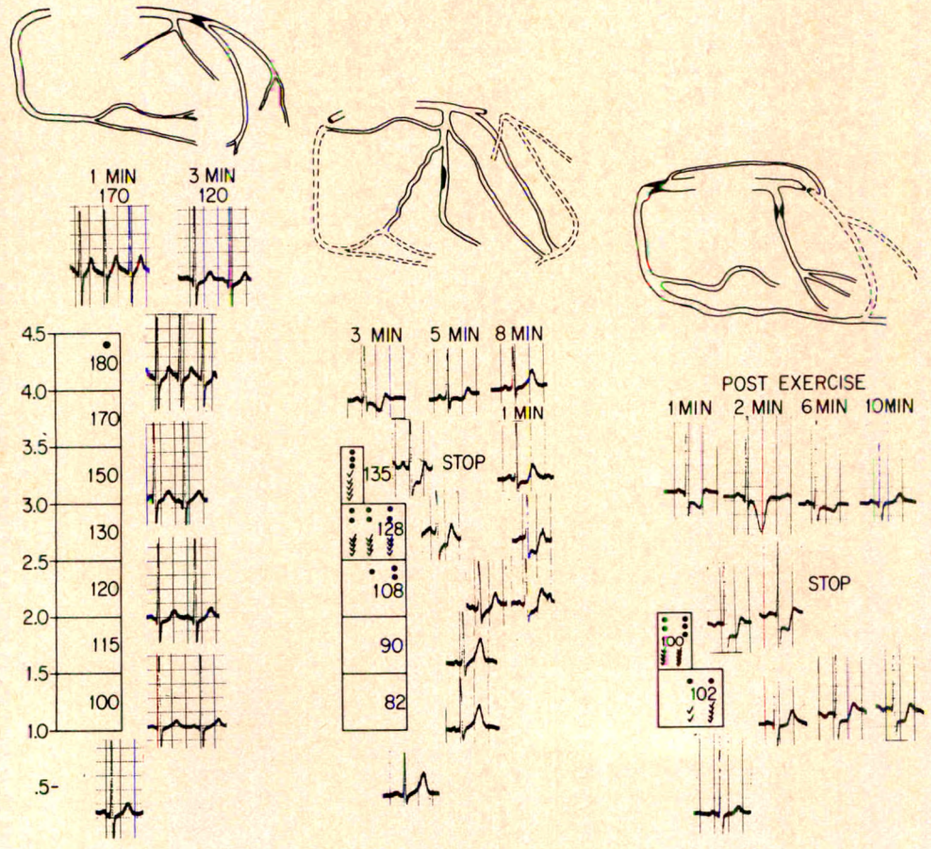

FIGURE 2. Three examples of standard treadmill tests showing diagrammatic representation of the test with each block representing 3 minutes of walking at 10 percent grade at the speed in miles/hour indicated by the top of the block. Maximal heart rate for each stage is inside each block. Dots at top of blocks indicate the severity of angina. The checks at bottom of blocks indicate millimeters of S–T segment depression. Electrocardiographic strips for appropriate stages are mounted to the right of the block diagrams. Sketches of coronary arterial anatomy as determined from coronary angiograms are above. **Dotted lines** indicate vessels filled by collateral vessels beyond the area of obstruction. Nonischemic response is shown on the left, ischemic responses in the center and on the right.

ing until ischemic manifestations in the form of anginal discomfort or S–T segment deviations, or both, make their appearance. In this way the work load imposed is tailored to the capacity of the patient and diagnostic accuracy is enhanced. Our test is designed to go beyond diagnostic capability to the determination of the patient's exercise tolerance as limited by the symptomatic manifestations of the disease—anginal pain, dyspnea, fatigue or leg pain. For this purpose, exercise is continued until the patient reaches a symptomatic end point score of 3+, indicating symptoms of moderately severe intensity (in our scoring system 1+ indicates mild, 2+ moderate, 3+ moderately severe and 4+ maximally severe intensity). This stopping point provides a tolerance test of good reproducibility that is useful for following up the course of the disease and the effects of therapeutic intervention, drugs, surgery or exercise training.[4]

Intelligent use of exercise testing of any type requires an understanding of the behavior of the electrocardiogram as it is influenced by exercise, recognition of the ischemic response, appreciation of the false positive and false negative response as well as the effects of certain electrocardiographic patterns that might distort the results.

The Ischemic Response

Figure 2 illustrates three treadmill tests performed in our laboratory. The graphic scheme representing the sequential stages is accompanied by (1) electrocardiographic strips obtained with use of a bipolar transthoracic lead showing the patterns at various stages, and (2) drawings of the coronary arterial anatomy as disclosed by coronary cineangiograms. In the case illustrated on the left, exercise performance was normal, and there were no anginal symptoms or ischemic manifestations in the electrocardiogram. This patient had previously demonstrated Prinzmetal's variant angina[5] with nocturnal episodes of pain and S–T segment changes as well as mild angina at the 4 miles/hour stage of the treadmill test. The normal response illustrated occurred after 1 year of daily walking exercise. The local stenotic lesions in the left anterior descending coronary artery remained the same upon repeat study. Completion of the 4 or 4.5 miles/hour stage of the test at 10 percent upgrade represents a performance equal to a maximal effort for the average sedentary adult American man. No deviation of the T waves or S–T segments occurred either during or after exercise in this high work load test.

The center panel of Figure 2 illustrates an ischemic response in a man who has achieved an improvement of capacity during a program of daily walking exercise. He was stopped by 3+ angina at the 3.5 miles/hour stage. Ischemic depression of the S–T segment appears coincident with the onset of anginal distress, and the degree of depression increases as the intensity of the pain builds up to the 3+ end point. The postexercise recovery period is associated with deep T wave inversion and then gradual return to the normal pattern. The arteriogram demonstrated total

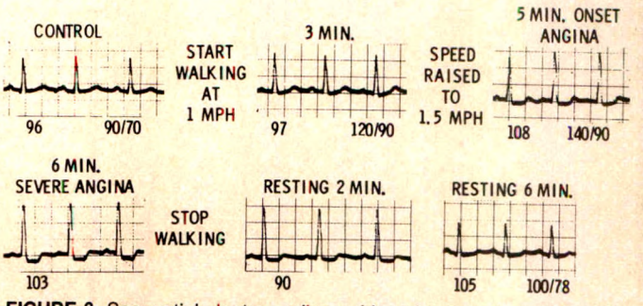

FIGURE 3. Sequential electrocardiographic strips from treadmill test of a patient with severe angina, poor exercise tolerance and extensive three vessel coronary obstructive disease. MPH = miles/hour.

occlusions in both the left anterior descending and the right coronary arteries with collateral filling beyond the occlusions. Severely ischemic S–T depression is usually seen over areas of myocardium supplied primarily by collateral circulation.

The third panel of Figure 2 illustrates a poor performance by a severely disabled man who was halted by 3+ angina in the second stage of the test at a low work level. Very severe ischemic depression is seen during exercise and very marked T inversion is seen during the recovery period. Total occlusion of the left anterior descending artery and severe stenoses in the left circumflex and right coronary arteries reduced coronary perfusion to all parts of the heart.

The ischemic electrocardiographic responses shown in Figure 2 represent advanced and unmistakable changes. One cannot expect to find such typical changes in all cases, nor can one expect to find consistent relations between the degree of S–T segment depression and the intensity of anginal symptoms or the extent of impaired coronary perfusion. For example, the patient whose electrocardiograms are shown in Figure 3 had such severe anginal pain at a low working level that he could not progress beyond the 1.5 miles/hour stage of the standard treadmill test. With severe pain there was only 1 mm of horizontal S–T segment depression and no T wave inversion in the postexercise recovery period. His coronary angiogram showed total occlusion of the right coronary artery with collateral filling distally, total occlusion of the left circumflex artery with preservation of a large marginal branch and severe stenosis in the proximal left anterior descending system—advanced three vessel disease yet minimal electrocardiographic changes provoked by exercise.

The ischemic response is not always manifested by S–T segment depression. Figure 4 displays electrocardiographic strips from an exercise test in which the angina was accompanied by marked S–T segment elevation. This response occurred in a man whose only coronary arterial lesion was a single high grade stenosis in the proximal left anterior descending coronary artery. The pattern must be very rare because we have seen it only a few times, mostly in persons who have had a prior myocardial infarction. This patient had never had an infarct.

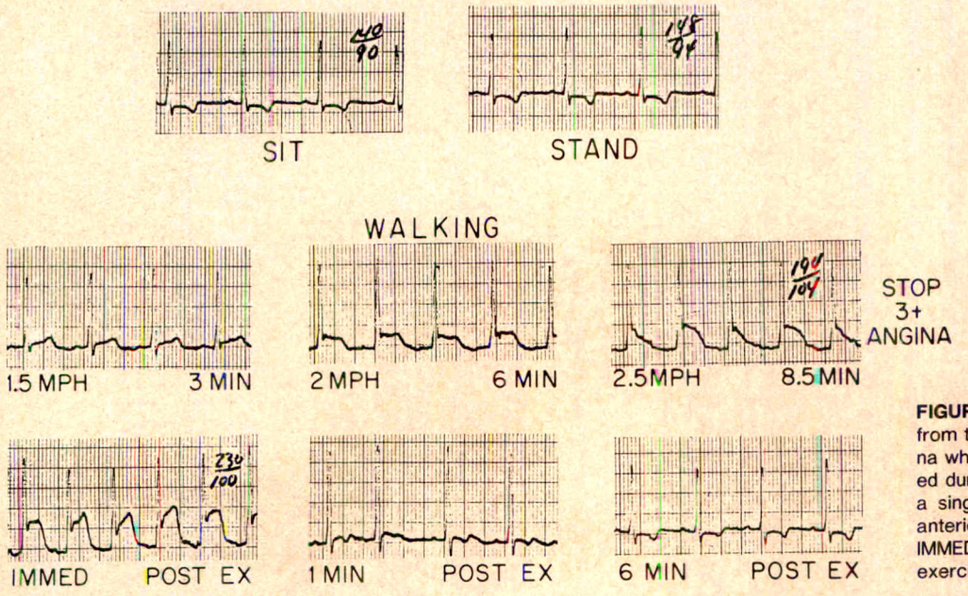

FIGURE 4. Electrocardiographic strips from treadmill test of a patient with angina whose S–T segments became elevated during pain. Ischemia was caused by a single high grade stenosis of the left anterior descending coronary artery. IMMED = immediately; POST EX = post-exercise.

The Problem of J Point Depression

The development of junctional or J point depression with the S–T segment remaining in an upward slanting orientation frequently causes uncertainty in interpretation of exercise electrocardiograms. This finding in the large series of subjects with long-term follow-up reported by Robb and Marks[6] was not associated with an increased prevalence of coronary events and thus has been regarded by many as a non-ischemic or perhaps innocent electrocardiographic manifestation. In our experience, J point depression is often a stage in the development of the ischemic response. Figure 5 illustrates two treadmill tests performed 3 months apart. In the first test the patient was stopped at the 3.5 miles/hour stage by fatigue, but he was experiencing mild substernal heaviness. In the second test, performed after a 10 lb weight loss and a program of a daily walking exercise, the pattern of J point depression finally evolved into a clearly ischemic pattern as the S–T segment became horizontal in the 4 miles/hour stage and he was stopped by dyspnea and angina. The ischemic pattern persisted into the postexercise recovery period. Cause of the ischemia was a high grade stenosis of the left main

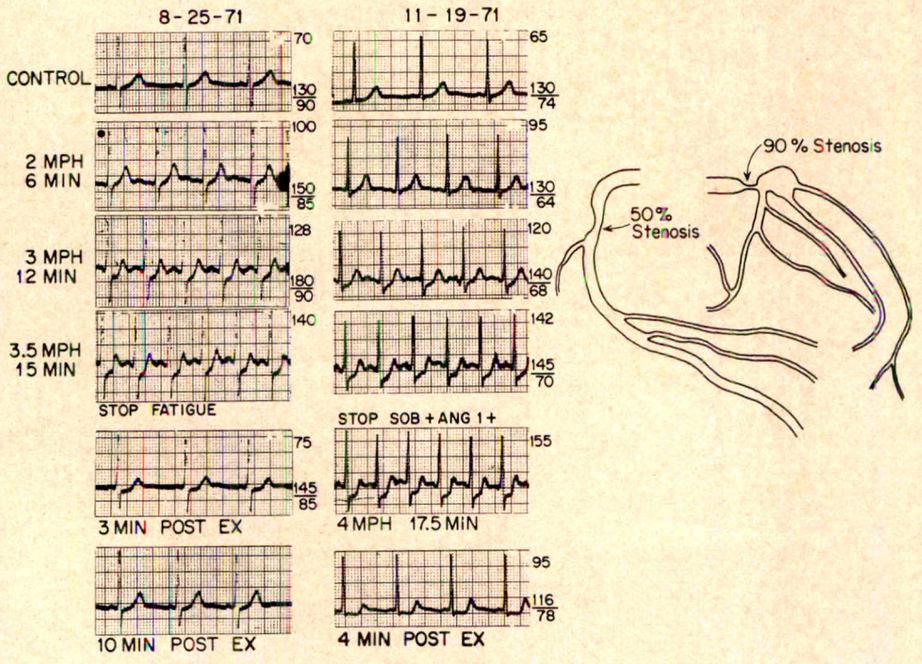

FIGURE 5. Two treadmill tests 3 months apart performed by a patient with mild angina. The first test resulted only in J point depression, but the second test yielded a classic ischemic response. Coronary angiograms disclosed high grade stenosis of the left main coronary artery. ANG = angina; SOB = shortness of breath.

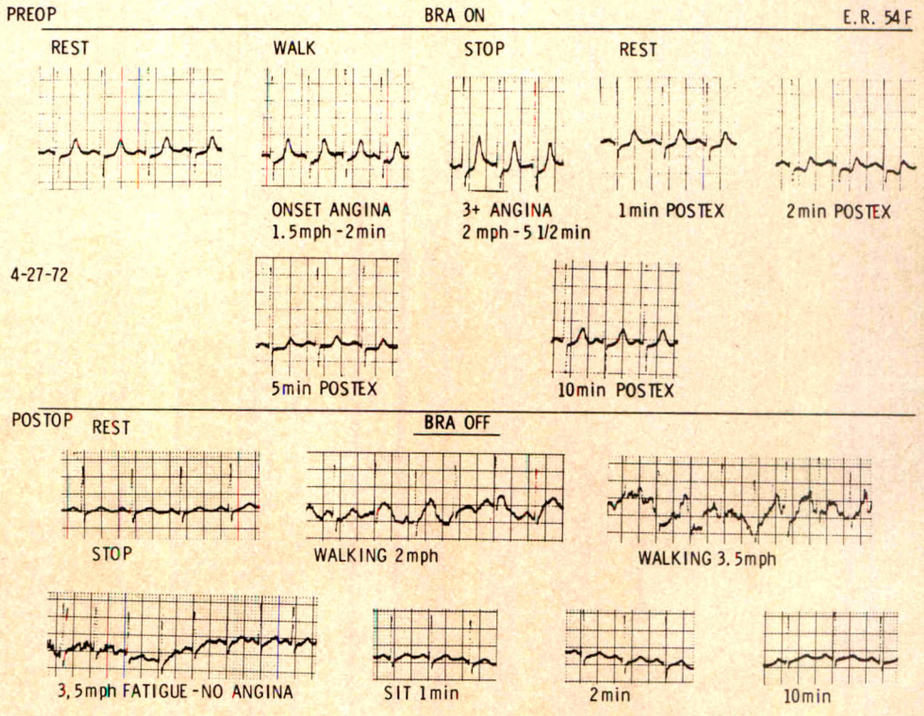

FIGURE 6. Electrocardiographic strips from two treadmill tests performed by a patient who had a good result from a saphenous vein bypass graft operation. In the preoperative test **(top)** the ischemic response emerges in the postexercise period. The postoperative test **(bottom)** demonstrates improved capacity and absence of ischemia, but the tracing is marred by motion artefact caused by uncontrolled motion of the bosom.

coronary artery proximal to an aneurysmal poststenotic dilatation.

In some instances we have been able to confirm the ischemic origin of J point depression by sublingual administration of nitroglycerin to the patient during treadmill walking and by observing the regression of this electrocardiographic pattern and disappearance of angina as walking continued at a steady pace. Thus, J point depression may indeed be a manifestation of myocardial ischemia, but it cannot be interpreted with reliability unless confirmatory evidence can be generated: the presence of typical anginal distress, the eventual emergence of the typical ischemic pattern either during or after exercise, or the demonstrated presence of significant coronary arterial obstruction.

Postexercise Ischemic Pattern

Ischemic S–T depression sometimes emerges only in the recovery period after exercise. The top panel of Figure 6 shows the sequential electrocardiographic changes during and after a standard treadmill test of a 54 year old woman who was stopped at the 2 miles/hour stage with 3+ angina. J point depression present at the end of exercise evolved into a clearly ischemic downslanting depression in the postexercise period, leaving no doubt about the ischemic nature of the response. Figure 6 also illustrates two other points. One is that treadmill testing is useful for assessing the results of coronary artery bypass graft surgery. The test at the bottom was conducted 3 months after a single saphenous vein graft bypassing a high grade stenosis in the left circumflex coronary artery. Great improvement in exercise tolerance is shown by completion of the 3.5 miles/hour stage of the test without ischemic manifestations. The second is that an important technology enters into the recording of adequate electrocardiographic tracings during exercise. The extensive low-frequency motion artefact seen in the lower record occurred because the patient was not wearing a brassiere on the day of that test. Motion of the bosom during brisk walking causes pulling and tugging of the skin to which the electrode at the V_5 position is attached. Use of a brassiere usually avoids this form of motion artefact, as in the top record. Detailed instructions for placement and fixation of electrodes to obtain optimal recording fidelity have recently been published by the American Heart Association.[7]

In some patients with a severe ischemic response to exercise, the postexercise period is characterized by marked bradycardia. In Figure 7 a strong vagal influence is suggested by a series of junctional escape beats before the return of slow sinus rhythm and then a gradual reversion to a normal rate. The vast majority of bradycardic responses do not progress to this extreme degree of slowing.

A rare cause of postexercise bradycardia is the development of atrioventricular block. The patient whose electrocardiogram is shown at the bottom of Figure 7 had first degree heart block during exercise with progressive P–R prolongation in the postexercise period eventually leading to a brief episode of Wenckebach mechanism followed by recovery.

The Abnormal Resting Electrocardiogram

When a T wave inverted in the resting electrocardiogram becomes upright during exercise-induced

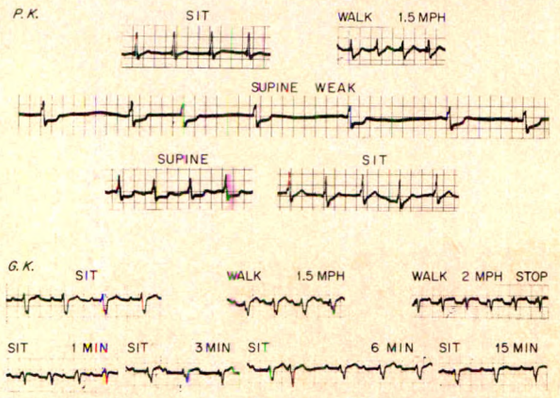

FIGURE 7. Electrocardiographic strips from treadmill tests performed by two subjects, one **(top)** demonstrating marked bradycardia in the postexercise period and the other **(bottom)** with first and second degree heart block.

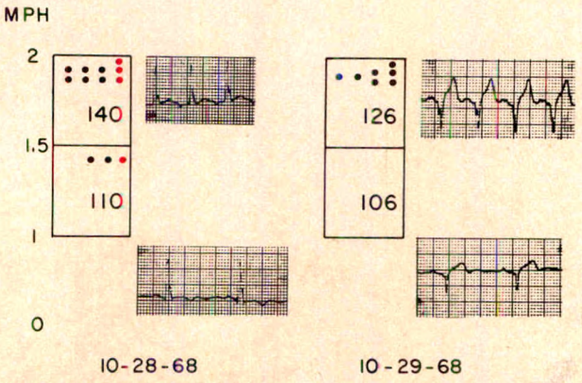

FIGURE 8. Treadmill test results of a man with angina and prior myocardial infarction whose inverted T wave became upright in lead V_5 during angina **(left)** and whose S–T segment became markedly elevated over the area of the infarction in lead V_2 **(right).** (Reprinted by permission from Kattus and MacAlpin.[8])

angina the question arises whether this reversal of T wave polarity represents an ischemic response. The problem is illustrated in Figure 8 in which the electrocardiogram of a patient with severe angina and an old anteroseptal myocardial infarct demonstrated a negative T wave in lead V_5 which became upright when the patient was stopped by 3+ angina. On the next day when the monitoring electrode was placed at the V_3 position, the site of the QS complex from the old infarct, striking S–T segment elevation was found at the time of 3+ angina. It was thus concluded that the strong influence of the repolarization potentials seen over the area of infarction were also influencing the surrounding areas. The significance of the S–T segment elevation is not entirely clear. We have seen it in patients after infarction even though they have no symptoms with vigorous exercise. We believe that this response does not in itself indicate myocardial ischemia but is an electrical consequence of the physical forces that occur at the boundary between scar tissue and contracting myocardium as though there were a temporary ventricular aneurysm during exercise at the site of the healed infarct. Thus, reversal of T wave polarity near the site of an old infarct cannot be regarded as reliable evidence of myocardial ischemia.

The series of tests recorded in a man with angina and a healed anteroseptal myocardial infarct (Fig. 9) illustrate another perplexing problem. With all tests conducted using the same electrocardiographic lead system (negative electrode at RV_6 position and positive electrode at V_5) there was initially S–T segment depression with the occurrence of 3+ angina. Four months later after an exercise training program there was slight improvement of exercise tolerance, but the S–T segment was elevated when 3+ angina occurred.

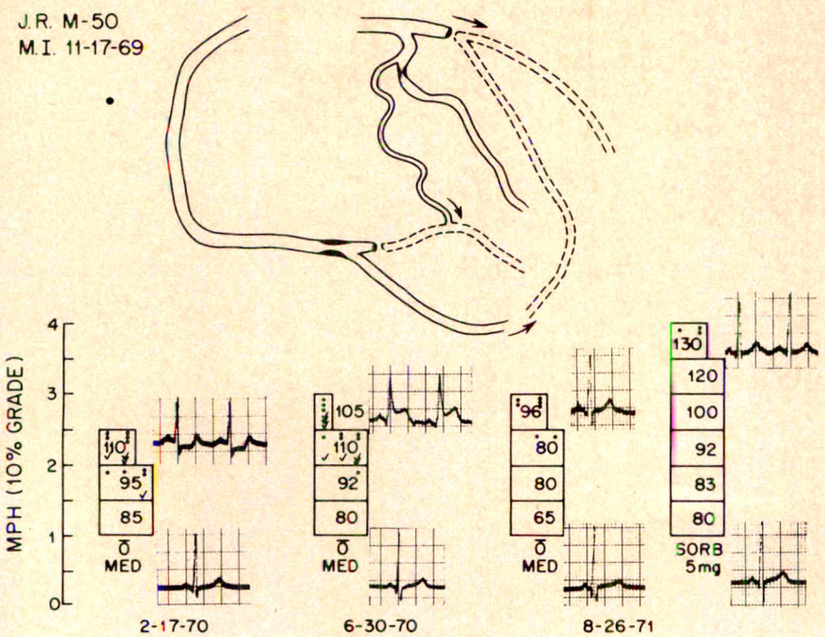

FIGURE 9. Sketch of coronary arterial anatomy **(top)** and sequential treadmill tests performed by a 50 year old man with residual angina after an anteroseptal myocardial infarction in November 1969. In the first test, the S–T segment is depressed; in the second test it is elevated; in subsequent tests, it is unchanged. Ō MED = no medication; SORB = premedication with isosorbide dinitrate.

On the third test, the S–T segment was unchanged with the same intensity of angina, and was also unchanged on a fourth test, when the patient had a greatly improved performance under the influence of isosorbide dinitrate absorbed from the buccal membrane. These findings suggest that the influence of S–T segment elevation from the region of the healed infarct may have dominated the second test, whereas the subendocardial ischemia of the noninfarcted muscle may have dominated the first. In the third and fourth tests the two influences may have canceled out each other. It must be concluded that interruption of the normal pathways of depolarization as in myocardial infarction lead to abnormal pathways of repolarization; these alterations may distort the display of S–T segment changes during ischemia, thus rendering them uninterpretable.

Bundle Branch Block

Distortion of the repolarization pathway in bundle branch block may obscure the ischemic response or produce a deflection that resembles ischemia but is not. Figure 10 shows the development and regression of a rate-related left bundle branch block in an asymptomatic man who has excellent exercise tolerance, normal ventricular contractility and widely open coronary arteries. During exercise the S–T seg-

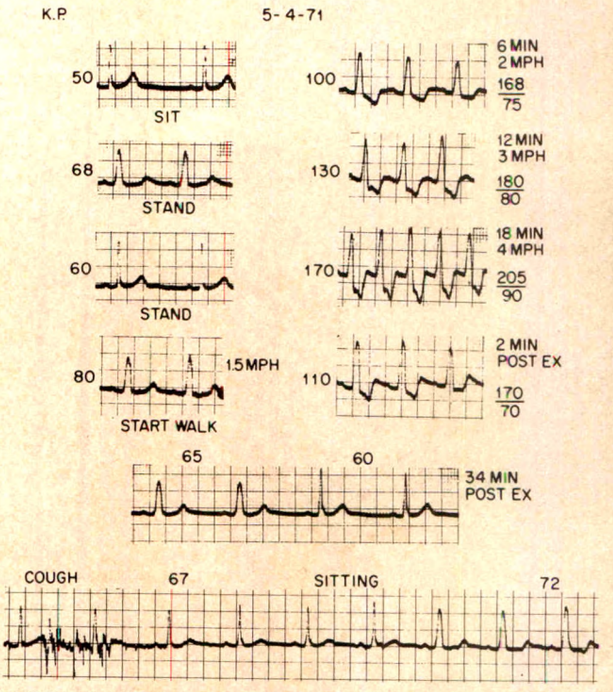

FIGURE 10. Electrocardiographic strips from a treadmill test performed by an asymptomatic man with rate-related left bundle branch block. He has good exercise tolerance and no coronary arterial obstruction.

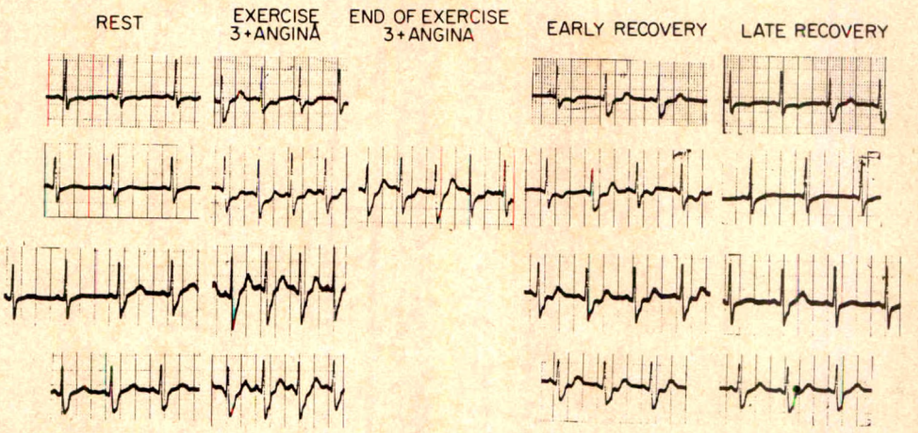

FIGURE 11. Electrocardiographic strips from four treadmill tests performed over a 2 year period by a man with severe angina and intermittent right bundle branch block which is at first exercise-induced but later becomes established. The ischemic response is readily seen in normally conducted beats but is obscured in the beats with bundle branch block.

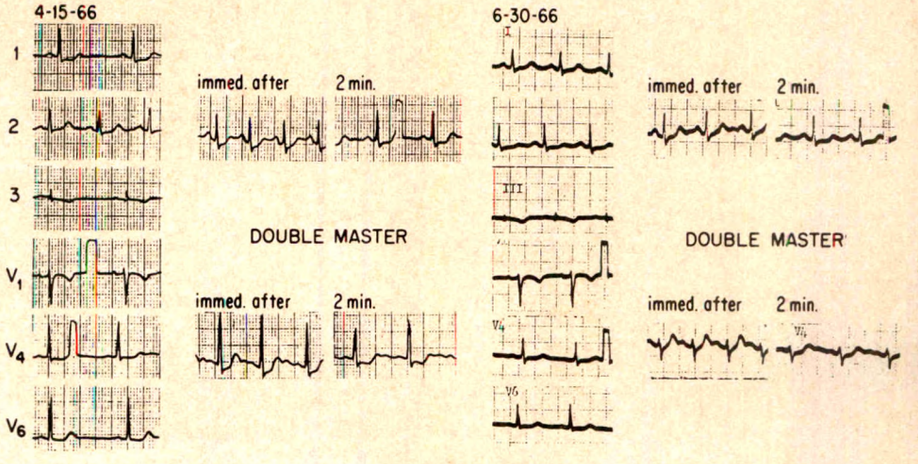

FIGURE 12. Electrocardiographic strips from double Master tests performed by a young woman at first when she was taking digitalis-containing reducing pills and again when she had discontinued these pills for 2 months. (Reprinted by permission from Kattus et al.[10])

ments are deeply depressed, but this alteration is due not to ischemia but to the abnormal pathway of repolarization secondary to the aberrant activation pathway.

Right bundle branch block also alters repolarization and thereby may obscure the ischemic effect on the S–T segment. In Figure 11 a sequence of treadmill runs shows intermittent right bundle branch block finally evolving into fixed right bundle branch block. During the period of intermittency the ischemic pattern provoked by exercise can be seen in the normally conducted beats but not in the bundle branch blocked beats. Later downslanting of the S–T segments is seen in the postexercise segments, but the classic ischemic pattern formerly present has been obscured by the conduction defect.

False Positive Ischemic Responses

Drug effects: S–T segment depressions closely resembling the ischemic pattern but not caused by ischemia have been recognized. Among the most common are those due to drug therapy. Digitalis glycosides may produce a pattern[9] such as that seen in Figure 12. On the left of the illustration are a resting electrocardiogram and strips from a double Master test in which an ischemic pattern was found. The tracings are from a 21 year old healthy woman who had been taking weight-reducing pills, among which one turned out to be digitalis presumably given for its anorectic effect. A repeat two-step test performed 2 months after discontinuation of the drug yielded a normal response.

The studies shown in Figure 13 were performed in a young physician who had experienced an episode of sharp stabbing chest pain. The dramatic postexercise ST–T wave inversions were not associated with discomfort. The rounded configuration of the trough of the inverted T wave resembled the pattern of digitalis effect. The patient denied taking digitalis but admitted that he had been treating himself for mild hypertension with reserpine and chlorothiazide. Several weeks after he stopped taking these agents, a normal exercise performance was elicited. It is believed that some degree of potassium depletion was responsible for the unusual T wave pattern that emerged in the postexercise electrocardiogram.

Vasoregulatory asthenia: A pattern that we have encountered at least three or four times a year is one that has often led to erroneous diagnoses of coronary artery disease. Holmgren et al.[11] in Sweden have called it the syndrome of vasoregulatory asthenia. Its features are illustrated in Figure 14. The patient usually complains of ill-defined chest pains not well correlated with exertion and not usually convincing evidence of angina. The electrocardiogram often manifests S–T sagging or T wave inversion when the patient stands up. With exercise there is usually an inappropriate acceleration of the heart rate at low work levels, and the S–T segments become depressed as in Figure 14. These changes are abolished or drastically modified by beta adrenergic blockade induced by propranolol. They may be entirely abolished by a period of mild exercise training such as walking 2 miles every day. Coronary arteriograms in patients with these findings disclose no obstructive disease in the blood vessels. The syndrome is believed to be due to excess adrenergic drive or perhaps excess responsiveness to adrenergic influence. In our experience it has

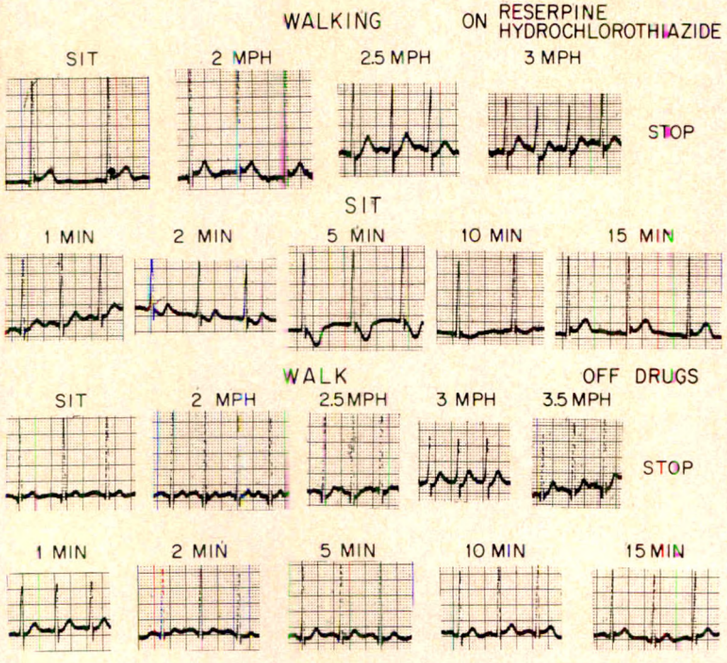

FIGURE 13. Electrocardiographic strips from treadmill tests performed by a young man who was taking reserpine and chlorothiazide during the first run and had discontinued these drugs for 2 months at the time of the second run.

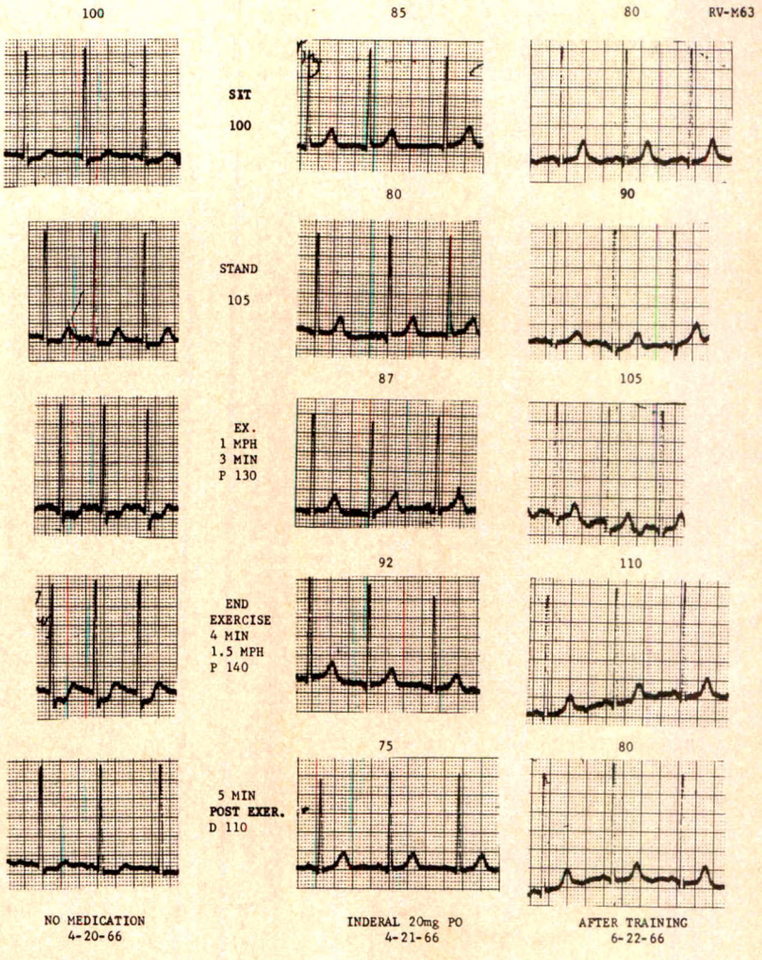

FIGURE 14. Electrocardiographic strips from three treadmill tests performed by a 63 year old man who was stopped by leg claudication pain at a low work level but who had no anginal pain. During the first run, the patient was taking no medication. The second test was performed after oral administration of 20 mg of propranolol (Inderal®) and the third after 2 months of a daily walking program of 1.5 miles/day performed in stages as permitted by leg pain. The changes in the first test are attributed to vasoregulatory asthenia. P and D = pulse rate. (Reprinted by permission from Kattus et al.[12])

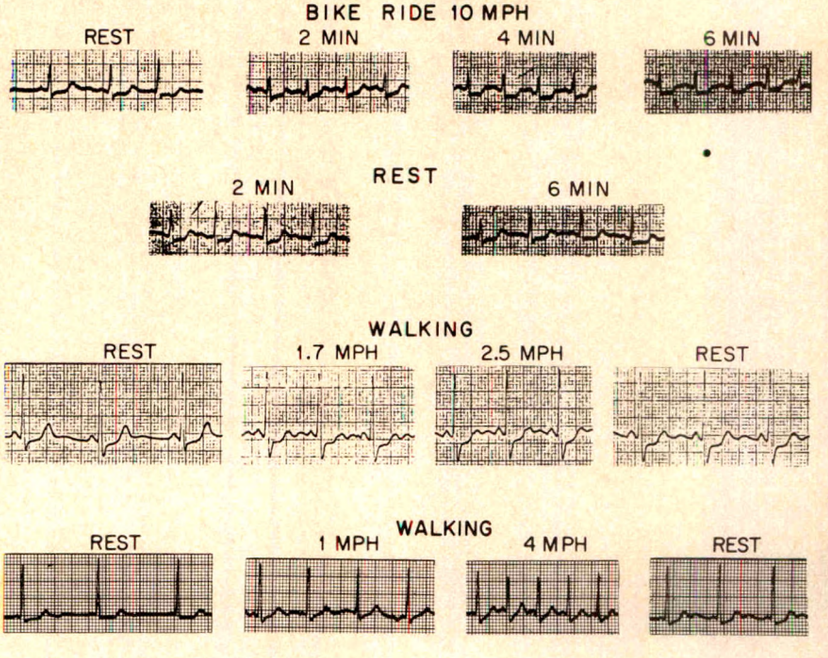

FIGURE 15. Top, electrocardiographic strips recorded before, during and after bicycle exercise in a patient who did not have pain during the test but stopped because of fatigue. She had marked pectus excavatum. **Bottom,** two treadmill tests performed by a patient with a short P–R interval. The first test was conducted with the negative electrode on the manubrium and the positive electrode at the V_5 position. During the second test, the negative electrode was in the right axilla.

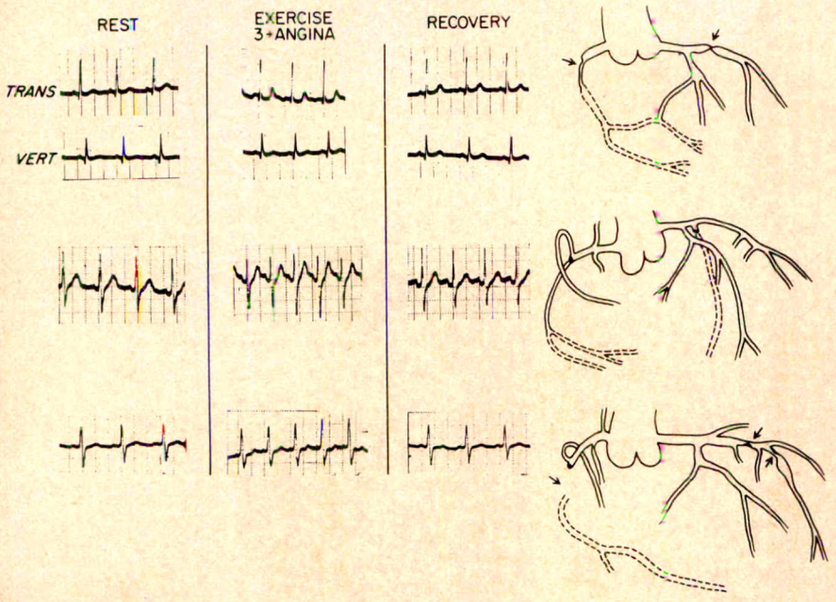

FIGURE 16. Electrocardiographic strips from treadmill tests performed by three patients who had no S–T segment shifts during 3+ angina. Transthoracic leads were recorded in all, and the first also had a vertical lead. All three subjects had prior inferior myocardial infarction. Sketches of the coronary arterial anatomy are at right.

a good prognosis, and we have never known a coronary event to occur in such a patient.[12]

Chest deformity: Two uncommon causes for false positive electrocardiographic responses to exercise are shown in Figure 15. At the top are strips from a bicycle exercise test in a woman who had vague chest pain. No pain was elicited during the test, and the S–T segment depression found was essentially similar before and after the exercise. Angiograms revealed normal coronary arteries. We believe her electrocardiographic pattern was due to a marked pectus excavatum. We have seen three other patients with this chest deformity who had similar electrocardiographic findings with exercise testing.

Effects of atrial potentials: The lower panel of Figure 15 represents a false positive test due to the effect of the atrial repolarization wave on the S–T segment. The patient, an asymptomatic woman, has a short P–R interval of 0.11 second. In the first test the monitored electrocardiographic lead has the negative electrode on the manubrium and the positive electrode at the V_5 position. This lead is aligned along the axis of the P wave and tends to amplify the effects of the atrial potentials. Thus, the S–T depressions associated with the amplified TA wave led to the appearance of an ischemic response. When the negative electrode was placed in the right axillary line, the lead axis became more perpendicular to the P wave axis and the influence of the TA wave was greatly lessened in this patient with the Lown-Ganong-Levine syndrome.[13]

False Negative Responses

False negative electrocardiographic responses occur in about 10 percent of subjects who undergo testing. These patients have typical anginal distress during exercise without an accompanying pattern of ischemia on the electrocardiogram. The vast majority of these responses are found in subjects who have survived prior myocardial infarction. The tracings in Figure 16 are from three such subjects, all of whom had old healed inferior myocardial infarcts and Q waves in leads II, III and aVF but normal findings in the precordial leads. None of these patients had S–T segment deviation during exercise-induced 3+ angina. In each case multiple lead positioning did not reveal the expected changes. The coronary angiograms of these patients suggested that the angina was due to ischemia of the anterior myocardial wall since each had obstructive disease in the left anterior descending coronary system in addition to the total occlusion of the right coronary artery that had produced the previous infarcts. The reason for the failure of the ischemic electrocardiographic pattern to emerge is not apparent, but the typical character of the anginal pain, its relation to exercise and its response to nitroglycerin left no doubt about its ischemic origin. Thus in such cases when the presence of myocardial ischemia is clearly defined by other means including the resting electrocardiogram and arteriogram the classic ischemic electrocardiographic pattern is not a necessary component of a valid exercise test for exercise tolerance. In this situation the anginal symptom can be taken at face value even though the electrocardiographic proof is lacking.

Conclusion

This discussion has been concerned with the recognition of ischemic electrocardiographic responses as they are elicited by exercise testing under controlled conditions. Such changes have to do with the form of the depolarization and repolarization phases of the cardiac action potentials. The extensive problem of cardiac dysrhythmias as they are provoked by exer-

cise have been purposely avoided since another paper appearing in this Symposium is concerned with this subject.

The conclusions that may be drawn are (1) that the exercise electrocardiogram must be continuously monitored during testing since changes may be expected from moment to moment, and (2) that good fidelity of recording must be assured by careful attention to electrode placement and fixation to avoid motion and positional artefacts. When properly obtained, the exercise electrocardiogram is a powerful diagnostic tool for identifying myocardial ischemia and assessing its severity. Accurate interpretation of the results demands an awareness of the variations of patterns that might be expected, the possibilities of false positive and false negative responses and the misleading effects of pharmacologic and metabolic influences.

Disturbances of Cardiac Rhythm and Conduction Induced by Exercise

Diagnostic, Prognostic and Therapeutic Implications

Alterations of cardiac rhythm and conduction occur frequently during exercise stress testing and may provide significant information regarding cardiovascular status. Exertion may induce arrhythmias as a result of sympathetically enhanced phase 4 depolarization of ectopic foci or the induction of myocardial ischemia secondary to increased myocardial oxygen demand. Exercise may abolish arrhythmias present in the resting state, an effect attributed to overdrive suppression and inhibition related to sinus tachycardia. Although a wide spectrum of electrophysiologic changes may be elicited by stress testing, ventricular dysrhythmias are of primary importance. Premature ventricular contractions that are frequent, multifocal, repetitive or associated with light work loads have been particularly indicative of coronary artery disease. Exertional ventricular irritability has been observed more frequently in patients with coronary atherosclerosis involving two or more coronary vessels and accompanied by abnormalities of left ventricular wall motion. Exercise testing may have advantages over portable monitoring in the detection of ventricular arrhythmias. The mere presence of ventricular ectopic beats at rest does not preclude carefully performed graduated stress testing nor does their disappearance during effort exclude the presence of coronary artery disease.

Disturbances of cardiac rhythm and conduction are commonly observed during exercise stress testing and may provide important clinical information on cardiovascular status. Thus, exertion-induced ectopic ventricular rhythms may be of diagnostic,[1,2] prognostic[3] and therapeutic[4] significance in coronary artery disease. In addition, exercise stress testing has been utilized to evaluate the role of arrhythmias in patients with syncopal episodes and to assess the efficacy of antiarrhythmic therapy.[5] In this paper we review current knowledge of the electrophysiologic response of the heart to physical exertion and examine directions for future investigation.

Electrophysiologic Effects of Exercise

Exercise is capable of inducing a number of alterations in the electrical activity of the myocardium, the net result of which may be either enhancement or inhibition of ectopic rhythms and abnormal conduction. Derangement of cardiac electrophysiology as a response to exercise is unpredictable in an individual subject, and cardiac rhythm and conduction may vary as a function of the level of exertion or stress. Figure 1 illustrates physiologic alterations accompanying exercise and their possible sequelae.

Pathophysiologic basis for arrhythmias during exercise: The stress of exertion frequently results in the appearance of arrhythmias not present in the resting state. The production of such arrhythmias by exercise has been attributed to heightened sympathetic tone, increased myocardial oxygen demand, or a combination of these fac-

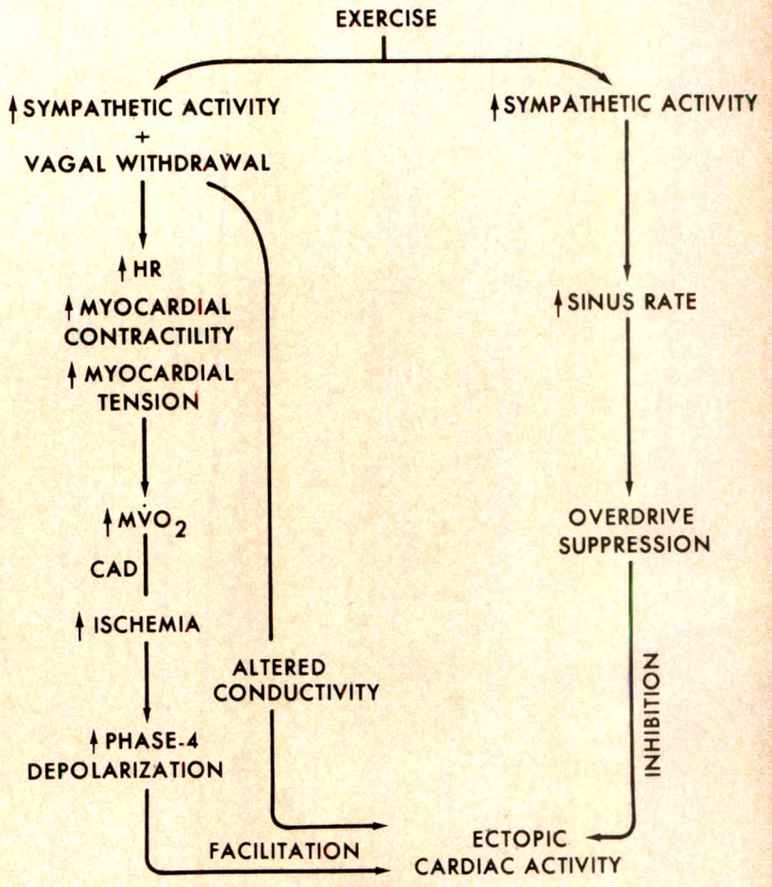

FIGURE 1. Physiologic alterations accompanying exercise. ↑ = increased; ↓ = decreased; → = unchanged.

tors. Augmented sympathetic drive to the myocardium may provoke ectopic Purkinje pacemaker activity by accelerating the rate of phase 4 depolarization at this site, enhancing its spontaneous discharge and thereby increasing automaticity.[6,7] Increased myocardial oxygen demand, when not matched by oxygen supply, results in local tissue hypoxia. Myocardial hypoxia produces temporal dispersion of depolarization and repolarization as well as alterations in conduction velocity and thereby provides an ideal substrate for the appearance of arrhythmias related to both automaticity and reentry.[8] Thus, myocardial ischemia may act as the stimulus for the appearance of abnormalities of rhythm and conduction during stress testing.

Myocardial ischemia is a common response to exercise stress in the presence of coronary artery disease. Myocardial oxygen consumption ($M\dot{V}O_2$) is determined by heart rate, contractility and intramyocardial tension.[9] The effect of exercise upon these factors augments $M\dot{V}O_2$ and thus may result in myocardial ischemia if oxygen demand exceeds supply. This disparity is usually a consequence of the restricted flow reserve of the coronary circulation in coronary atherosclerotic disease. Such an imbalance may be related not only to elevated levels of exercise stress, but also to events in the immediate postexercise period. At this time, peripheral arteriolar dilatation induced by exercise, and reduced cardiac output resulting from diminished venous return secondary to the abrupt cessation of muscular activity, may combine to produce a reduction in blood pressure and decreased coronary perfusion while the heart rate is still increased. Thus, a pathophysiologic basis for the occurrence of arrhythmias at various points during exercise stress is indicated.

Abolition of arrhythmias by exercise: Although the precipitation of arrhythmias by exercise is widely recognized, abolition during exercise of ectopic cardiac activity present at rest is a less appreciated phenomenon. The ability of exercise to abolish arrhythmias present in the resting state has generally been attributed to two mechanisms, both of which are related to the sinus tachycardia resulting from vagal withdrawal and increased sympathetic stimulation accompanying exercise. Thus, sinus tachycardia may inhibit an ectopic focus before its intrinsic discharge reaches threshold potential, an example of overdrive suppression. In addition, there is evidence[10] that rapid stimulation may result in decreased automaticity of Purkinje tissue and thus sinus tachycardia may inhibit automaticity of an ectopic focus.

Spectrum of Exercise-Induced Alterations of Rhythm and Conduction

Supraventricular arrhythmias: A wide variety of supraventricular arrhythmias may be noted in the process of stress testing. Wandering or ectopic atrial pacemakers and sinus arrhythmias are particularly common after exercise.[5] However, although 3 to 5 beat episodes of paroxysmal atrial and junctional tachyarrhythmias occurred frequently during exertion in 3,000 patients studied by Gooch,[5] sustained bouts lasting more than 15 seconds occurred in only 5 patients. Several investigators[2–5] have noted that atrial fibrillation and flutter are only rarely induced by exertion and, when they do occur, revert spontaneously. Indeed, observation of the response of ventricular rate to various levels of activity has provided an excellent method of assessing adequacy of digitalization in patients with atrial fibrillation.[11] This response could not be predicted from the resting heart rate. Finally, rare episodes of sinoatrial block and sinus arrest have been noted during stress testing, usually after termination of exercise.[5]

Conduction defects: Alterations of cardiac conduction involving both the atrioventricular (A–V) node and bundle branches may occur during the course of exercise testing. A–V conduction is accelerated during exertion under normal circumstances[12] and absence of such shortening has been regarded as an abnormal response indicative of A–V junctional block. In addition, the appearance of frank first degree heart block or its progression to more advanced block has also been noted in association with exercise.[2–5] Conversely, preexisting block of the A–V node has been noted to decrease in this setting, a phenomenon that may be related to enhanced conduction velocity due to increased sympathetic stimulation.

Abnormalities of ventricular conduction consisting of intraventricular conduction defects and bundle branch block involving either the left or right bundle branch were observed in 8 of 733 patients undergoing stress testing.[5] Seven of these eight patients had clinical evidence of heart disease. Sandberg[2] reported on a small group of patients who manifested bundle branch block during exertion and in whom the appearance of the defect with mild effort was associated with clinical evidence of cardiac disease. In both of the latter studies the abnormalities of conduction were usually preceded by evidence of incomplete block in the resting electrocardiogram, and they appeared during exercise and disappeared after termination of the stress.

Ventricular arrhythmias: Ectopic beats and tachyarrhythmias of ventricular origin have been frequently described during exercise testing.[13–16] Thus, ventricular dysrhythmias with exertion were noted in 39 percent of patients by Kosowsky et al.,[16] in 31 to 49 percent by McHenry et al.,[14] in 20 percent by Goldschlager et al.[13] and in 30 percent by Blackburn et al.[15] Ectopic ventricular beats were observed most commonly in the postexercise period in all but one study[15] and frequently occurred late in the recovery period. Thus, two thirds of the arrhythmias in one report[1] occurred within 2 minutes of cessation of exercise and the single death reported in a large group of patients with coronary disease occurred suddenly 4 minutes after completion of the exercise test.[13] Salvos of ventricular tachycardia were preceded by single ectopic beats in the vast majority of cases. Premature ventricular contractions occurred with increased frequency with advancing age[14] and higher levels of effort[14,15] of the patients evaluated.

Diagnostic Significance of Ventricular Arrhythmias Precipitated by Exercise

Considerable interest has been stimulated in the diagnostic and prognostic implications of ventricular dysrhythmias occurring during graded bicycle or treadmill exercise testing. Although the significance of these rhythm disturbances has not been firmly established, certain patterns seem evident on the basis of the information currently available.

Debate continues on the significance of exercise-induced ventricular extrasystoles as indicators of the presence of organic heart disease. Several early investigations[17–20] demonstrated the occurrence of ventricular dysrhythmias in apparently normal persons and failed to find a correlation between ventricular ectopic beats elicited during effort and clinical evidence of cardiac disease. Sandberg[2] found that the subset of patients who demonstrated ventricular arrhythmias after light effort also manifested clinical heart disease, and Gooch and McConnell[1] related bursts of ventricular tachycardia to the presence of cardiac abnormalities. These conclusions were supported by McHenry and associates[14] who, while observing ventricular ectopy in more than one third of apparently normal subjects, noted an even greater frequency of ventricular dysrhythmias in patients with clinically evident or suspected cardiac disease. In the patients manifesting these abnormalities, ventricular ectopic beats were provoked by lighter exertion and at lower heart rates and had a greater tendency to be frequent, multifocal or repetitive. In all these studies the criteria for heart disease were based upon clinical evidence; thus, subclinical cardiac abnormalities may well have been present and undetected in the "normal" group.

Zaret et al.[21] evaluated exercise-induced ventricular irritability in a group of patients undergoing coronary arteriography and found coronary atherosclerosis in 72 percent. Multiple vessel disease was significantly more common than in matched patients without arrhythmias. Goldschlager et al.[13] compared a group of patients with ventricular arrhythmias elicited by exertion with a group of patients without such disturbances who had undergone cardiac catheterization and coronary arteriography. These investigators found significant coronary stenosis in 89 percent of patients with exercise-precipitated ventricu-

lar extrasystoles. In addition, they observed a significantly greater prevalence of double and triple vessel coronary artery disease and abnormal left ventricular motion in this group than in patients with coronary disease without arrhythmias. Provoked arrhythmias occurred more frequently during the recovery period in this study. A striking finding was the disappearance of ectopic beats during exercise stress in a high percentage of patients with significant coronary disease.

Although there is no question that ventricular arrhythmias may occur in the absence of organic heart disease, certain conclusions appear justified from the findings cited: (1) Ventricular arrhythmias provoked by exertion occur significantly more frequently in patients who have cardiac disease than in normal subjects; (2) ventricular ectopic beats that occur with minor increases in heart rate, or demonstrate high frequency, multifocal pattern or repetitive firing are particularly suggestive of cardiac disease; (3) patients with coronary atherosclerosis who have ventricular rhythm disorders induced by stress testing have a greater frequency of multiple vessel disease and abnormalities of wall motion; and (4) the termination of ventricular ectopy during exertion does not indicate the absence of flow-limiting coronary atherosclerosis.

Prognostic Significance of Exercise-Induced Ventricular Arrhythmias

Of major interest is the prognostic significance of exercise-induced ventricular arrhythmias. Premature ventricular contractions manifested in a resting electrocardiogram[22,23] or during activities[24] have been associated with an increased incidence of coronary atherosclerosis, subsequent mortality and sudden death.[15] This risk is especially prominent in patients with known cardiovascular abnormalities.[25] However, the resting electrocardiogram has a substantially lower yield than exercise electrocardiography in the detection of ectopic ventricular rhythms.[16] It would seem reasonable that ectopic ventricular beats evoked during exertion might carry serious prognostic implications and thus be of major importance in the issue of sudden death.[26] Long-term epidemiologic studies will be required to provide a definitive answer to this question. However, exercise-elicited ventricular extrasystoles have already been correlated with the coronary risk factors of hypertension and glucose intolerance as well as with ischemic electrocardiographic abnormalities and enlargement of the cardiac silhouette on roentgenographic study.[3] Indeed, in this study population, sudden death occurred in two patients with exertional ventricular irritability. That such potential disasters may be amenable to therapy is suggested by Bryson et al.,[4] who reported in these patients exertional ventricular tachycardia and fibrillation which prompted coronary arteriography, revealing significant coronary atherosclerosis. Subsequently these arrhythmias were abolished by coronary artery bypass graft surgery.

Usefulness of Holter Monitoring Versus Exercise Stress in the Detection of Arrhythmias

Premature ventricular beats elicited by exertion can be evaluated either by prolonged ambulatory monitoring, a costly and time-consuming procedure, or by graded exercise testing. Kosowsky et al.[16] compared the sensitivity of ambulatory electrocardiographic monitoring and treadmill exercise testing in revealing ectopic ventricular activity in 81 patients with and without coronary artery disease. Of 66 patients with a normal resting electrocardiogram, prolonged monitoring was positive for arrhythmias in 27 percent, whereas exercise was positive in 39 percent. Exercise also revealed serious rhythm abnormalities that would not have been suspected by use of monitoring alone. These authors therefore concluded that stress testing was superior to portable electrocardiographic monitoring in the detection of ventricular irritability. In this regard, Blackburn et al.[15] demonstrated a 35 percent increase in the yield of premature ventricular complexes and of multiform and repetitive ventricular ectopic beats during maximal as opposed to submaximal exercise testing. Obviously, these additional arrhythmias would be detected by portable monitoring only if the patient performed activities requiring maximal exertion.

We have been impressed with the capacity of both exercise stress testing and prolonged portable electrocardiographic monitoring as means of detecting ventricular ectopic rhythms. Of 22 patients with angiographically documented coronary artery disease, 5 (23 percent) manifested ventricular ectopic beats on the resting electrocardiogram. Ventricular premature beats developed in 59 percent during exercise and were detected in 82 percent of the group by 10 to 12 hour portable monitoring during normal activity.[27]

Effects of Physical Conditioning on the Frequency of Premature Ventricular Complexes

The effect of physical conditioning on ectopic ventricular beats has not been definitely established. Blackburn et al.[15] evaluated the response of ectopic ventricular beats to physical conditioning in 196 middle-aged, "high risk" men free of clinically manifest heart disease. These previously sedentary subjects were evaluated before and 18 months after a program of progressive exercise conditioning. Among subjects adhering well to the program there was inconclusive but suggestive evidence that the work threshold for ventricular ectopic activity was increased. This finding certainly merits further investigation.

Ventricular Irritability and Termination of Exercise Testing

In light of these data, certain practices have evolved in our laboratory concerning ventricular irritability and the performance of exercise stress testing. Thus, the presence of ectopic ventricular beats in a patient whose condition is otherwise stable immediately before study is not considered a contraindica-

tion to exercise testing. Exercise is begun slowly at low work loads and is terminated on occurrence of significant increase in frequency of ectopic beats or dangerous ventricular arrhythmias such as frequent multifocal extrasystoles, R on T phenomenon, coupled ventricular beats or runs of ventricular tachycardia. In our experience exercise testing has infrequently required interruption because of ventricular arrhythmias. Upon completion of exercise the patient is seated with legs elevated to increase venous return, and the electrocardiogram is carefully monitored for at least 6 minutes.

Indirect Assessment of Myocardial Oxygen Consumption in the Evaluation of Mechanisms and Therapy of Angina Pectoris

Exercise testing, applied in a systematic, standardized manner, is a more reliable means of assessing angina pectoris than clinical evaluation. In utilizing exercise testing to determine functional impairment in angina, it is essential to distinguish between external stress, or the load on the skeletal muscles, and internal or cardiac stress. This distinction is critical to meaningful evaluation of angina since the performance of the heart is of primary concern in this syndrome. Evaluation of external exercise capacity alone is limited as a measure of cardiac performance since the relationship between external function and cardiac performance may not be direct. A readily applicable approach to determination of cardiac functional capacity in angina is afforded by indirect assessment of myocardial oxygen consumption ($M\dot{V}O_2$). This is achieved through derived indexes of heart rate and blood pressure, two major determinants of $M\dot{V}O_2$, usually in the form of the product of heart rate × systolic blood pressure × systolic ejection period (triple product) or the product of the first two variables (double product). Although these indexes do not encompass all the major determinants of $M\dot{V}O_2$, they demonstrate a constancy at the point of angina in each individual that is consistent with the occurrence of this syndrome at a peak, critical threshold of $M\dot{V}O_2$ above which regional myocardial perfusion cannot rise. Utilization of indirect indexes of $M\dot{V}O_2$ allows evaluation of the mechanisms of action of a variety of conditions and therapeutic interventions in angina. Thus, enhanced perfusion of ischemic myocardium is suggested by augmentation of the triple product when angina occurs during exercise, as observed after successful aortocoronary bypass graft surgery. Medical therapy of angina acts through a fundamentally different mechanism demonstrated by reduction in the triple product at given levels of exercise with no increase at the point of angina, thus indicating a major effect on the circulatory response to the physical stress. Indirect indexes of $M\dot{V}O_2$ are thus useful in interpreting mechanisms and evaluating therapy of angina but they must be applied with appropriate caution because of their inherent limitations.

Appreciation of the pathophysiology of angina pectoris has provided a rational approach to the diagnosis and treatment of this disorder. The systematic application of exercise in evaluation of angina has played a significant role in advancing physiologic understanding of the syndrome. Exercise has been utilized not only in diagnosis but also as an objective means of assessing clinical severity and investigating the circulatory dynamics associated with angina. Relation of the latter alterations to cardiac energetics in terms of myocardial oxygen consumption ($M\dot{V}O_2$) has been of major importance in elucidating the mechanisms of angina, quantifying functional impairment and clarifying modes of therapy in this syndrome.

Value of Exercise Testing in Assessment of Angina

Although the symptom of ischemic cardiac pain is the most overt manifestation of the anginal syndrome, assessment of symptomatology is of limited reliability in estimating severity of the disease because of the subjective nature of the symptom and the variability of provoking factors. Use of exercise testing to determine functional status has significantly extended clinical evaluation of the patient with angina. Measurement of exercise capacity provides a reliable, quantitative index of functional impairment in angina not attainable by clinical appraisal alone. Thus, systematic assessment of exercise capacity under controlled conditions in patients with angina yields reproducible results in terms of duration of exertion required to provoke the pain of myocardial ischemia.[1] However, underlying cardiac functional capacity is of primary concern in relation to severity of the disease in angina. Although exercise ability provides a functional index in patients with angina, it does not necessarily reflect cardiac capacity. In the response of the body to external work, the relation between skeletal muscle performance and the load sustained by the heart is not always direct,[2] thereby rendering this method of limited value as a precise indicator of cardiac performance. These qualifications also pertain to maximal total body oxygen consumption ($\dot{V}O_2$ max), traditionally considered the most reliable extracardiac index of overall cardiovascular functional capacity.[3,4] This quantity, like external exercise capacity, may also vary under certain conditions in its relation to cardiac performance during exertional stress.[5,6]

Extracardiac factors modifying response to exercise: It is now appreciated that many factors can modify the cardiac response to any given physical stress and thereby alter angina-limited exercise ability without changing cardiac functional capacity.[2] Among these are reduced environmental temperature,[2] emotional stress,[7] the postprandial state[2] and the acute effects of cigarette smoking,[8] which can, in themselves, augment myocardial mechanical effort. In addition, of course, conditions such as musculoskeletal or peripheral circulatory diseases that impair the function of organ systems other than the heart may significantly diminish exercise capacity. It is therefore apparent that exercise performance may be determined not only by the work load directly imposed on the skeletal muscles, but also by other ambient variables influencing the myocardium. This is exemplified by the reduction in exercise performance (decreased time to onset of angina) that accompanies reduced environmental temperature. In this setting, in which intrinsic cardiac functional capacity may be unchanged, decreased exercise performance is related to the augmented cardiac work load, indicated by the increased heart rate and blood pressure, associated with reduced temperature.[2] Similarly, the fasting state may be associated with enhanced exercise capacity in relation to onset of angina compared with exercise capacity in the postprandial state. Again, the altered performance is unassociated with change in cardiac function and is a result of the reduced work load on the heart, as determined by the circulatory response to a given physical stress, in the fasting state compared with that in the period after a meal.[2] Appropriate interpretation of the preceding results would be obscured if exercise capacity were assessed only in terms of duration of exercise before onset of angina. Thus, to the extent that extrinsic influences alter exertional capacity when anginal pain is the limiting factor, the value of this measure as a means of assessing cardiac performance is diminished.

Relation of $M\dot{V}O_2$ to Evaluation of Angina

It is apparent that an approach more closely reflecting the performance of the heart is required for meaningful evaluation of cardiac function in angina. It must encompass the distinction between external work, as entailed by the activity of the musculoskeletal system, and internal work, represented by the mechanical performance of the heart. The latter can be assessed in terms of cardiac energy utilization which, by virtue of the obligatory aerobic nature of myocardial metabolism,[9] is directly related to the oxygen consumption of the heart ($M\dot{V}O_2$).[10]

Peak $M\dot{V}O_2$: Angina is the result of an imbalance between myocardial oxygen demand and supply that is typically related to a restricted coronary circulation consequent to coronary atherosclerosis.[11] Coronary circulatory reserve is compromised and, in response to increases in $M\dot{V}O_2$, coronary blood flow, and thereby oxygen delivery, cannot be augmented beyond a limit fixed by the degree of arterial obstruction. The level of $M\dot{V}O_2$ at which the disparity between myocardial oxygen supply and demand occurs represents the internal or cardiac threshold for angina. Thus, peak $M\dot{V}O_2$ at the point of angina (hereafter referred to as peak $M\dot{V}O_2$) is an index of maximal tolerated cardiac stress, which is directly related to cardiac functional capacity in angina and may be independent of external work load as determined by the influence of extrinsic factors on the heart. In the absence of alterations in delivery capacity of the coronary circulation, as may occur with progression of coronary artery disease, $M\dot{V}O_2$ at the point of angina is constant for a given patient. Peak $M\dot{V}O_2$ also provides a relative measure of maximal attainable coronary blood flow since coronary blood flow follows $M\dot{V}O_2$ pari passu, as demonstrated both experimentally[12,13] and in man.[6] This relationship is a result of the exclusively aerobic pattern of cardiac metabolism, requiring near maximal oxygen extraction by the myocardium even under basal conditions, thereby precluding use of this mechanism for increasing oxygen supply. Alterations in $M\dot{V}O_2$ are therefore effected by changes in coronary blood flow.[14]

$M\dot{V}O_2$ at angina vs. $M\dot{V}O_2$ at given external work load: In addition to providing a measure of cardiac performance through peak $M\dot{V}O_2$, the foregoing relationships afford insight into mechanisms of therapeutic interventions and other factors that may

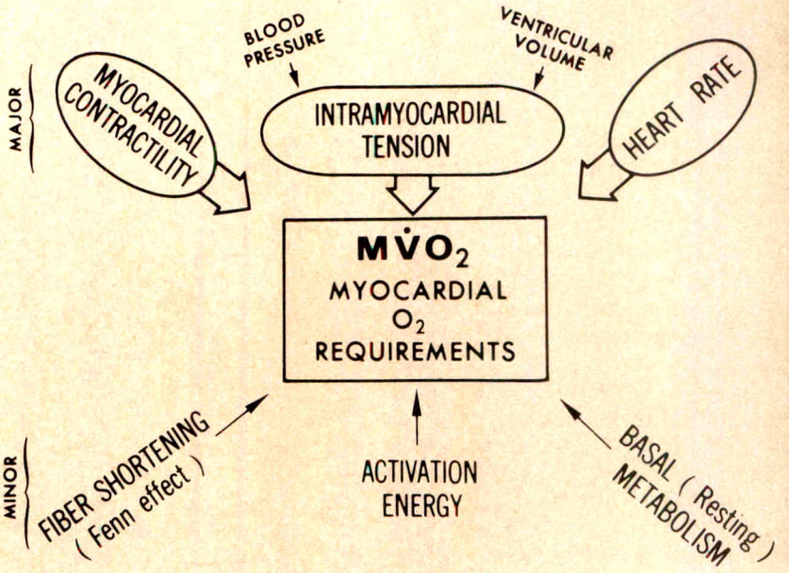

FIGURE 1. The major and minor determinants of myocardial oxygen consumption ($M\dot{V}O_2$).

alter exercise capacity in patients with angina. Therapy in angina is based on restoration of a favorable balance between myocardial oxygen demand and supply, thereby alleviating myocardial ischemia. This balance can be achieved by increasing oxygen supply or reducing demand.[15] An increase in peak tolerated $M\dot{V}O_2$ after an intervention is consistent with increased blood flow and oxygen supply to ischemic areas of myocardium. A decrease in peak $M\dot{V}O_2$ implies diminished myocardial perfusion and increased ischemia, and thus a lower level of maximal tolerated cardiac stress.

Interventions that enhance physical performance in patients with angina by reducing myocardial oxygen requirements are associated with no change in peak tolerated $M\dot{V}O_2$. However, myocardial mechanical effort at any given level of external work is decreased by these interventions and attainment of angina-limiting $M\dot{V}O_2$ is thereby delayed, allowing work of greater intensity and duration. Thus, as emphasized by Goldstein and Epstein,[16] valid interpretation of the mechanism of action of an intervention that alters angina-limited exercise capacity requires knowledge of $M\dot{V}O_2$ both at angina and at a given external work load. Reduction of myocardial oxygen requirements is achieved by attenuating the response to external stress of the hemodynamic variables upon which $M\dot{V}O_2$ is dependent. These include heart rate, intramyocardial tension (directly related to ventricular pressure and volume) myocardial contractility and certain minor factors (Fig. 1).[10] The rationale for this therapeutic approach is consistent with the demonstration of hemodynamic alterations indicative of increased $M\dot{V}O_2$ in association with angina that has been provoked by exercise,[17] catecholamine stimulation[18] or pacing-induced tachycardia[19] or has occurred spontaneously.[20]

Indirect indexes of $M\dot{V}O_2$ (heart rate-blood pressure product): $M\dot{V}O_2$ can be directly determined as the product of myocardial arteriovenous oxygen difference and coronary blood flow, but since both of these measurements require cardiac catheterization, this technique is not feasible for general application. However, indirect approaches to assessment of $M\dot{V}O_2$ have been rewarding as practical means of estimating this quantity. Consistent with their importance as major determinants of myocardial oxygen utilization, derived indexes comprised of blood pressure and heart rate have provided a reasonable approximation of relative $M\dot{V}O_2$. These have included the product of mean aortic pressure and heart rate,[13] the tension-time index[21] (product of the integral of left ventricular pressure during systole and heart rate), the triple product of heart rate, systolic blood pressure and systolic ejection period[7] and the double product of heart rate and systolic blood pressure.[6,22]

These indirect indexes of $M\dot{V}O_2$, although affording ease of assessment, also involve inherent limitations. Thus, they fail to include ventricular volume and the contractile state of the myocardium, two major determinants of $M\dot{V}O_2$. Whereas heart rate and blood pressure are readily determined, measurement of volume and contractility is complex and thus inconsistent with pursuit of a widely applicable approach to $M\dot{V}O_2$. Further, the significance of the duration of ventricular ejection (systolic ejection period) in influencing $M\dot{V}O_2$, and thus the relative advantages of the triple or double product, has been unclear. However, experimental[23] and recent clinical[6,22] studies have suggested that duration of ejection, initially considered a significant determinant of $M\dot{V}O_2$,[21] is relatively unimportant.

Despite these theoretical deficiencies, a close correlation has been demonstrated between $M\dot{V}O_2$ and the heart rate-blood pressure product during exercise in normal young men,[6,22] thus supporting the utility of indirect assessment of $M\dot{V}O_2$. In these studies, performed from the resting state through exercise to 56 percent of maximal capacity, there was a high cor-

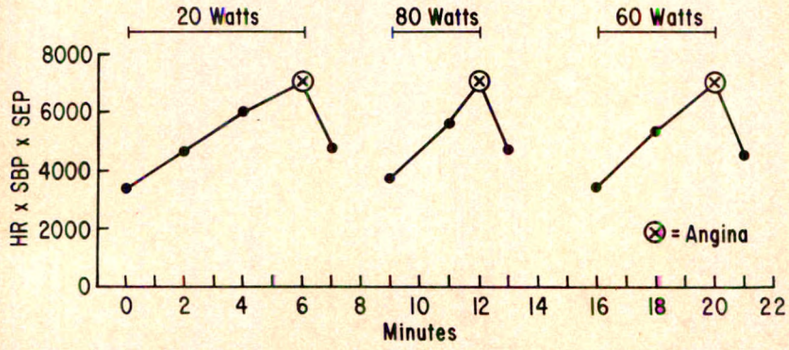

FIGURE 2. Relation of onset of angina to duration and intensity of exercise on the bicycle ergometer and the triple product of heart rate (HR), intraarterial systolic blood pressure (SBP) and systolic ejection period (SEP). Duration of exercise is inversely related to the work load but angina occurs at a constant triple product.

relation ($r = 0.90$) between $M\dot{V}O_2$ and the product of (1) heart rate × peak systolic aortic pressure, (2) heart rate × mean systolic aortic pressure, and (3) heart rate × mean aortic pressure. Heart rate alone also correlated closely with $M\dot{V}O_2$ ($r = 0.88$). The relationship between measured coronary blood flow and the preceding variables was similarly close. However, tension-time index and total body oxygen consumption ($\dot{V}O_2$) correlated less well with $M\dot{V}O_2$. Because these studies were performed in normal young men, appropriate caution is indicated in extrapolating the results to older patients with ischemic heart disease.

Application of Indirect Indexes of $M\dot{V}O_2$ to Angina

Although the importance of heart rate in the precipitation of angina was recognized more than 3 decades ago,[24] this relation was subsequently questioned,[25] and blood pressure was discounted as a significant factor in the production of angina in these early studies.[24,25] These findings may be related to limitations in methodology since they were derived from indirect, cuff blood pressure measurements[24,25] and data obtained after termination of exercise.[24] Recent reevaluation of the relation of heart rate and blood pressure to the occurrence of angina has confirmed the significance of both variables and upheld the applicability of indirect indexes of $M\dot{V}O_2$ to evaluation of angina. Thus, it has been demonstrated that for the individual patient, precipitation of angina occurs at a constant value for the triple product of heart rate, intraarterial systolic pressure and systolic ejection period.[7] This relationship is consistent and independent of variations in the type, intensity and duration of exercise (Fig. 2).[7] Thus, external exertional capacity, as indicated by intensity and duration of exercise, varies as a function of the imposed load. However, provocation of angina is related to attainment of a critical triple product that reflects the stress on the myocardium, the essential factor in the production of angina. These findings provide indirect support for the concept, discussed earlier, that each patient experiences angina at a critical or peak level of $M\dot{V}O_2$, which can be approximated by the triple product and is determined by the delivery capacity of the coronary circulation to the region of lowest threshold for imbalance between myocardial oxygen supply and demand.

Since heart rate-blood pressure indexes of $M\dot{V}O_2$ are constant at the point of angina for a given individual despite their failure to account for several principal determinants of $M\dot{V}O_2$, it is reasonable to conclude that under the conditions of study, the omitted factors either are constant or are so altered that their effects on $M\dot{V}O_2$ are canceled. In such instances, $M\dot{V}O_2$ would, in effect, vary as a function of the readily measurable hemodynamic variables, blood pressure and heart rate, as suggested by the previously cited studies in normal man.[6,22] Whether these findings pertain to ischemic heart disease has not been definitively determined.

Application of rate-pressure product to interpretation of pathophysiology of angina: With use of derived indexes of heart rate and blood pressure to estimate $M\dot{V}O_2$, it is possible to clarify mechanisms of angina occurring under various circumstances. Thus, exercise in the postprandial state is accompanied by an elevated triple product at any given level of external work in comparison to the response in the fasting state, and angina occurs earlier. However, the triple product at the point of angina is the same in the two states.[2] These data suggest that the diminished exercise capacity after a meal is the result of an augmented circulatory response—that is, more rapid increase in heart rate and blood pressure—to exercise associated with this condition and is not related to changes intrinsic to the myocardium and coronary circulation. The unaltered triple product at angina is consistent with the latter conclusion. Likewise, the diminished exertional ability and earlier provocation of angina during exercise after smoking a cigarette is associated with an increased rate-pressure product above that occurring in the control exercise state.[8] An augmented circulatory response to physical exertion at low ambient temperature is similarly productive of angina after less exercise.[2] These studies, which implicate extramyocardial mechanisms in the alteration of exercise capacity under the conditions cited, demonstrate the application of indirect indexes of $M\dot{V}O_2$ to interpretation of pathophysiology in angina.

Evaluation of Therapeutic Mechanisms in Angina by Indirect Assessment of $M\dot{V}O_2$

It has generally been concluded that medical therapy is beneficial in angina pectoris by attenuating the circulatory response to physical or emotional stress.[1-5]

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

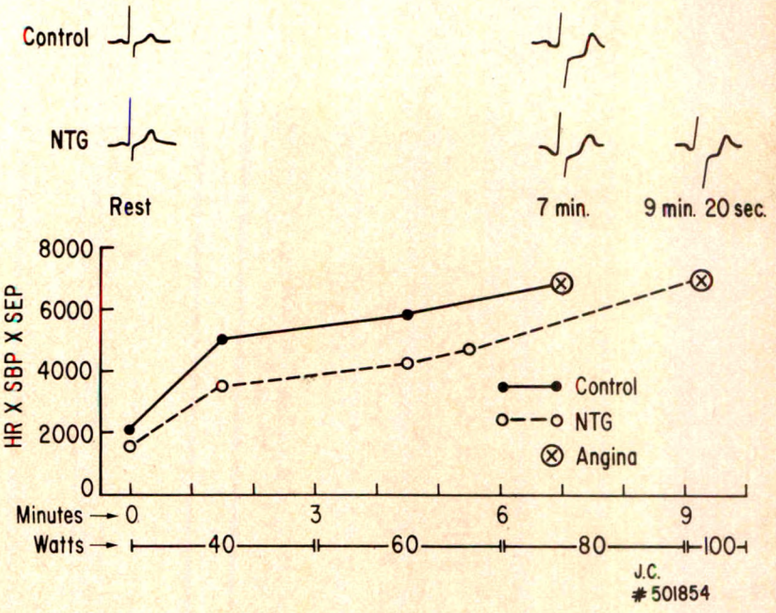

FIGURE 3. Exercise performance on the bicycle ergometer in a patient with coronary heart disease, before and after sublingual administration of nitroglycerin (NTG). The triple product (HR × SBP × SEP) is reduced after administration of nitroglycerin, resulting in increased exercise capacity. However, the triple product at angina is unchanged. Ischemic S–T segment depression (lead V_5) is delayed after administration of nitroglycerin until greater exercise performance has been achieved. Abbreviations as in Figure 2.

Thus, the nitrites and beta adrenergic blocking agents are associated with a reduced rate-pressure product and a delay in attainment of angina threshold. The beneficial effects of the hemodynamic actions of these drugs thus result in enhanced exertional capacity.

Effect of nitrites in angina: The effects of nitroglycerin on exercise performance, the triple product and the exercise electrocardiogram in a patient with ischemic heart disease are demonstrated in Figure 3. After nitroglycerin, ability to perform more exercise is related to a lower triple product at levels of work comparable to those imposed before nitroglycerin. Angina occurs at the same triple product as before administration of the drug but its onset is delayed. These findings, which are consistent with a primary therapeutic action on the hemodynamic determinants of $M\dot{V}O_2$ rather than improvement in myocardial perfusion, have been demonstrated by others for nitroglycerin[26,27] and sublingually administered isosorbide dinitrate.[27] In addition, direct measurement of coronary blood flow at the point of exercise-induced angina before and after nitroglycerin demonstrated no change in peak coronary flow[28] associated with enhanced exercise capacity. This finding is in accord with the results obtained utilizing indirect indexes of $M\dot{V}O_2$.

Although these indirect indexes are useful, their limitations may be appreciated in considering the effects of the nitrites in angina. Thus, the major hemodynamic action of the nitrites in decreasing $M\dot{V}O_2$ is reduction of ventricular volume,[29] the effects of which are not accounted for by the indirect methods. Further, the double product of heart rate and blood pressure is increased at angina after administration of the nitrites, which could be attributable to decreased ventricular volume or increased perfusion of ischemic myocardium. In this regard, it has been suggested that a separate effect of enhanced myocardial perfusion may play a role in the beneficial actions of the nitrites.[15] If such an effect were minor in relation to reduced myocardial oxygen demand, it would not

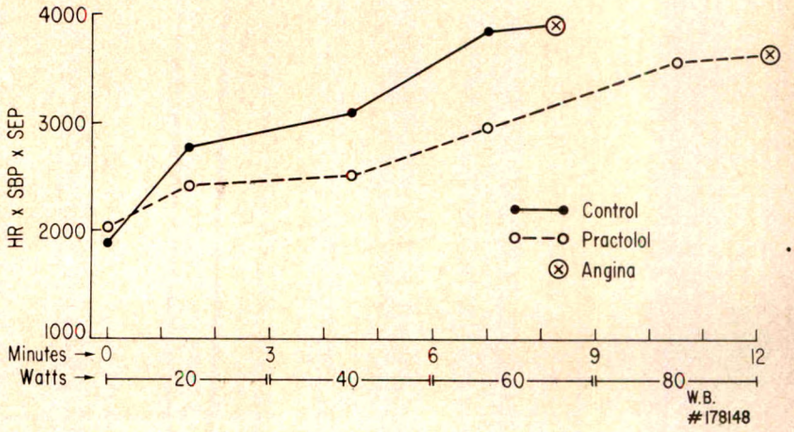

FIGURE 4. Exercise performance (bicycle ergometer) in a patient with coronary heart disease before and after cardioselective beta adrenergic blockade with intravenously administered practolol. The response to exercise of the triple product (HR × SBP × SEP) is attenuated after administration of the drug, resulting in increased duration and intensity of exercise before the onset of angina. Angina occurs at similar triple product before and after administration of the drug. Abbreviations as in Figure 2.

be discernible by indirect assessment of $M\dot{V}O_2$, since the latter methods reflect the resultant of the separate actions of any intervention on $M\dot{V}O_2$.

Effects of beta adrenergic blockade and carotid sinus nerve stimulation in angina: Improvement in effort tolerance by beta adrenergic blockade is consistent with a reduction in $M\dot{V}O_2$ in man during exercise.[15] As shown in Figure 4, the triple product is reduced for a given level of stress and angina is delayed. Although the triple product at angina after beta adrenergic blockade is similar to that of the control study in the example displayed, this finding is uncommon and our data[30] and those of others[31] generally demonstrate a reduction in triple product or rate-pressure product at angina after administration of beta adrenergic blocking drugs. Diminished myocardial oxygen requirement in response to a given level of exercise after propranolol has been confirmed in man by direct measurement of $M\dot{V}O_2$.[23] This may be related to a possible increase in ventricular size due to the depressant effect of these agents on myocardial contractility or to reduction in coronary blood flow. On the other hand, it has been suggested that propranolol may favorably redistribute coronary blood flow[32] and enhance release of oxygen from red blood cells to the myocardium.[33] These latter factors cannot be specifically delineated by indirect methods but the reduction of the rate-pressure product at angina after beta adrenergic blockade suggests that increased myocardial oxygen supply is not a major factor in the beneficial effects of these agents. The salutory effects of carotid sinus nerve stimulation in improving functional status in angina are also the result of reduced $M\dot{V}O_2$, as indicated by increased exercise ability without change in the triple product and reduction of the triple product at submaximal loads of exercise.[34]

Physical training in angina: Physical training, which may augment exertional ability in patients with angina, also appears to act by attenuating the response of the heart to physical stress.[5,35] Thus, the triple product is lower at a given external work load after a training program.[5] The increase in triple product at angina in some trained patients has been interpreted as a possible indication of enhanced myocardial perfusion.[5] However, this could be related to changes in other factors not reflected in the triple product, among them attenuated adrenergic response to exercise stress after a conditioning program,[35] which would reduce $M\dot{V}O_2$ by reducing myocardial contractility while simultaneously allowing attainment of a higher triple product.

Aortocoronary bypass graft: The effects of aortocoronary saphenous vein bypass graft on indirect indexes of $M\dot{V}O_2$ differ from those of other therapeutic modalities previously considered in this discussion and suggest a fundamentally different mechanism of action. Thus, we have evaluated the triple product during exercise in patients with angina before and after coronary bypass graft surgery. Our findings in patients with patent grafts are exemplified in Figure 5. There has been no consistent effect on the triple product during exercise at given work loads before and after operation. However, the triple product at angina before surgery has been exceeded in association with patent bypass grafts and angina has occurred at a markedly greater triple product or exercise capacity has been augmented to the point of volitional fatigue without angina,[36] as depicted in Figure 5.

Similar results have been reported by others comparing the rate-pressure product before and after aortocoronary bypass graft surgery, but utilizing cuff blood pressure.[37] It has been suggested that im-

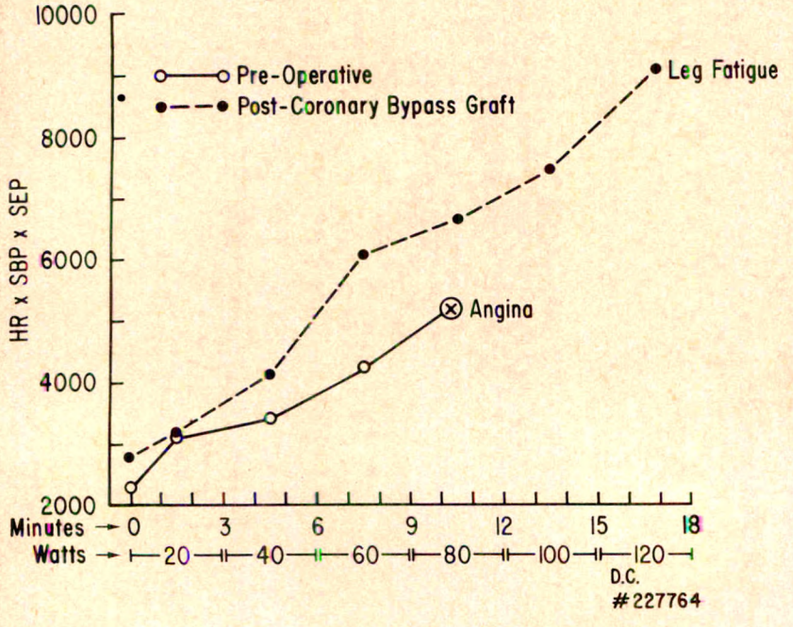

FIGURE 5. Exercise performance (bicycle ergometer) in a patient with coronary heart disease, before and after aortocoronary saphenous vein bypass graft surgery. The bypass graft is associated with increased exercise capacity, abolition of exercise-induced angina and elevated triple product, in contrast to the occurrence of angina with less exercise at a lower triple product before surgery. Abbreviations as in Figure 2.

proved clinical status and exercise capacity following aortocoronary bypass graft surgery may be related not only to graft patency, but also to intraoperative infarction of ischemic myocardium.[16,38] In a study in which this question was evaluated,[37] the great majority of patients with intraoperative infarction did not show clear improvement in exercise capacity as assessed by rate-pressure product and S–T segment changes during exercise although a few manifested enhanced function. The outcome in terms of cardiac capacity in such situations would appear to be the result of the interplay between the functional effects of the graft and the infarction, when the latter occurs.

Indirect indexes of $M\dot{V}O_2$ are of considerable use in the evaluation of angina. Within limits, they allow identification of the roles of external factors and intrinsic myocardial mechanisms in the provocation and therapy of angina. However, because they do not account for several major determinants of $M\dot{V}O_2$, findings based on their use must be interpreted with appropriate caution.

Experimental Observations on the Effects of Physical Training Upon Intrinsic Cardiac Physiology and Biochemistry

JAMES SCHEUER, MD, FACC*
SOMSONG PENPARGKUL, MD, PhD
ASHOK K. BHAN, PhD

Pittsburgh, Pennsylvania
Bronx, New York

Hearts of rats conditioned by a moderate swimming program for 8 weeks were compared with hearts of sedentary animals. Hearts of conditioned rats had greater mechanical responses to tachycardia and to increases in preload and afterload, in part because of improved coronary blood flow and oxygen delivery. Energy stores and intermediary metabolism could not account for improved performance of conditioned hearts. Changes in the properties of myocardial contractile proteins with conditioning were characterized by increased adenosine triphosphatase (ATPase) activity and rates of superprecipitation of actomyosin and by alterations in the availability of sulfhydryl groups at the active site of myosin. Hearts of conditioned rats were partially resistant to hypoxia. During hypoxia they converted chemical energy to external work with greater efficiency than hearts of sedentary rats.

The studies indicate that a moderate conditioning program in rats improves potential aerobic cardiac performance. Factors in this improvement include increased capacity for coronary flow and oxygen delivery and higher levels of actomyosin and myosin ATPase activity. Conditioning also confers partial resistance to hypoxia, apparently as a result of improved mechanisms of energy utilization.

Epidemiologic studies suggest that sedentary persons tend to have increased morbidity from cardiovascular diseases. Many investigations have demonstrated the effects of physical training on the integrated function of the cardiovascular system. The trained subject can attain a higher level of exercise and a greater maximal oxygen consumption than the untrained subject. This improved performance is achieved by way of increased cardiac output and peripheral oxygen extraction. The increased maximal cardiac output is associated with a lower heart rate at any level of exercise, but with the same maximal heart rate after physical training as before. Stroke volume is greater at any level of cardiac output in the physically trained state than in the sedentary state. In patients with coronary artery disease, physical training causes heart rate and cardiac output responses similar to those of normal persons. Some early results of training programs in patients who have recovered from myocardial infarction indicate that training may reduce the likelihood of reinfarction or sudden cardiac death.

Although the studies in intact man and animals are informative on the general effects of physical training, studies that elucidate some of the effects on physical training on the heart itself have only recently been conducted. The investigations described here were performed to determine whether physical training in rats affects intrinsic cardiac function, metabolism or biochemistry.

The Training Program

Male rats weighing 200 to 240 g were made to swim 75 minutes twice a day, 5 days a week, usually for 8 weeks. Matched sedentary control rats from the same shipment as the swimming animals were kept at normal cage activity for the same periods. Except for the swimming protocol the two groups were treated identically. The details of this protocol have been published previously.[1]

Perfused Heart Studies

To study the intrinsic mechanical function of these hearts as a pump and as a muscle, hearts were perfused in an isolated working rat heart apparatus with a bicarbonate buffer containing 5 millimolar of glucose.[2] The apparatus permits evaluation of cardiac function in the presence of a fixed aortic pressure and a controlled left atrial pressure, with the heart rate regulated by pacing and measurements made of coronary flow, cardiac output, left ventricular pressure and maximal rate of pressure rise (dP/dt), myocardial oxygen consumption and lactate and pyruvate production.

Cardiac function under steady state conditions: In the first series of experiments, hearts were perfused under steady state conditions for periods of 1 hour. Although the trained intact rats had bradycardia, when the hearts were perfused in the isolated perfusion apparatus without control of heart rate, the rates of hearts from sedentary animals and from conditioned animals were virtually identical. Under these steady state conditions, hearts from trained rats had greater cardiac output and external cardiac work than hearts of sedentary animals. Of more significance, the hearts of conditioned rats responded to a 15 percent increase in heart rate by an increase in cardiac work, whereas hearts of sedentary animals did not respond to tachycardia. With the increment in heart rate, myocardial oxygen consumption increased only in hearts of trained rats, whereas the production of lactate and pyruvate, products of glycolytic metabolism, increased with tachycardia only in hearts of sedentary animals.

Effect of increasing left atrial pressure: Figure 1 demonstrates the effects of increasing left atrial pressure on hearts of sedentary and conditioned animals in the working rat heart apparatus. The increase was associated with increased coronary flow only in hearts of conditioned animals. Cardiac output increased in both groups, but was significantly greater in hearts of conditioned rats than in hearts of sedentary control animals. Peak left ventricular systolic pressure and maximal dP/dt also increased to a greater extent in hearts of conditioned animals. When the heart was made to contract isovolumically by clamping the aortic tubing, the left ventricular pressure and dP/dt levels were higher in hearts of conditioned rats. Therefore, in terms of cardiac output, pressure and dP/dt, hearts of conditioned ani-

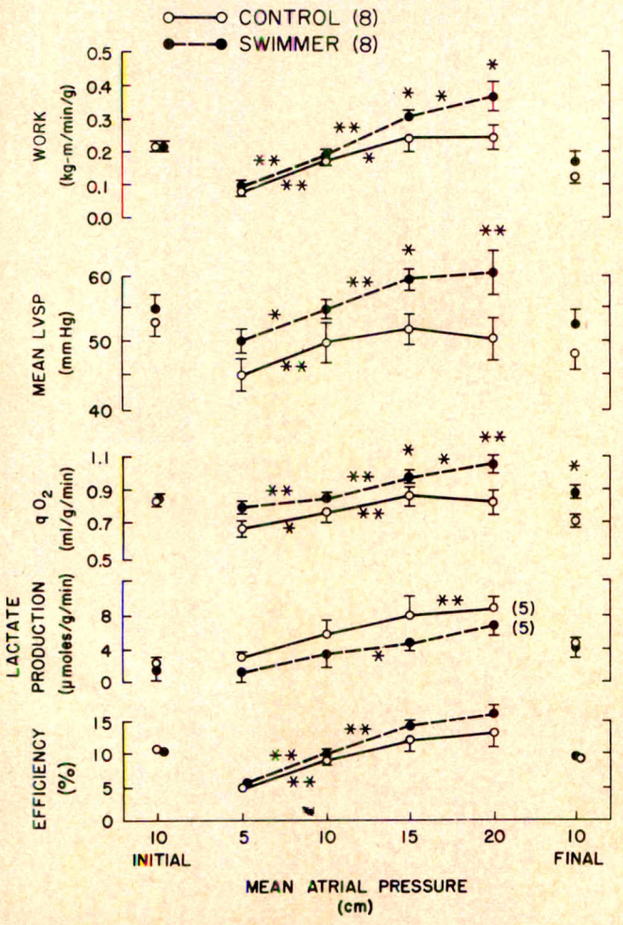

FIGURE 2. Effect of changing atrial pressure upon work, mean left ventricular systolic pressure (LVSP), oxygen consumption (qO_2), lactate production and efficiency. Designations as in Figure 1. FIGURE 3. Mechanisms of oxygen delivery to the myocardium with increasing atrial pressure. A–V O_2 = extraction of oxygen across the myocardium; CF = coronary flow per gram dry weight; qO_2 = myocardial oxygen consumption per gram dry weight. Symbols as in Figure 1.

mals had a greater cardiac reserve capacity to respond to the stress of increasing preload or afterload. Since hearts were contracting from the same end-diastolic pressure, the greater pressure and dP/dt achieved during isovolumic beats implies increased contractility in hearts of conditioned rats.

Figure 2 shows the results of the same experiments in terms of calculated work, mean left ventricular systolic pressure and metabolic measurements. With increasing atrial pressure, external work and mean pressure were greater in hearts of conditioned rats, as was myocardial oxygen consumption. Lactate production, the product of nonoxidative metabolism, tended to be greater in hearts of sedentary animals. Although cardiac efficiency increased with increasing atrial pressure in both groups, there was no significant difference between hearts of sedentary and conditioned rats.

Mechanism of oxygen delivery: Figure 3 shows the mechanism of oxygen delivery in these experiments.[3] Although oxygen consumption increased significantly with increasing atrial pressure in both groups, the increase was greater in hearts of conditioned rats. This increase in the conditioned animals was achieved by the increase in coronary flow and no change in the extraction of oxygen across the myocardium. In hearts of control animals, the increased oxygen delivery was achieved by a greater oxygen extraction and was not associated with an increase in coronary flow. This finding of increased oxygen extraction in hearts of sedentary rats without augmented coronary flow implies a limitation in coronary flow reserve in these animals and is consistent with previous observations[4–6] of increased myocardial vascularity induced in rats by physical training.

The ratio of oxidative to glycolytic adenosine triphosphate (ATP) formation was higher at all levels of cardiac work in the hearts of conditioned rats.[2]

Implications of studies: These studies in isolated perfused working rat hearts demonstrated that hearts from conditioned rats have a greater intrinsic cardiac reserve capacity to respond to tachycardia, increasing preload and increasing afterload in terms of cardiac output, pressure development and maximal rate of pressure development. The results imply improved potential function of the heart both as a pump and as a muscle. The mechanism of increased reserve appears to be in part a greater capacity for in-

creasing coronary flow and oxygen delivery in hearts of conditioned rats.

Studies on Energy-Related Metabolism

Energy Stores and Energy Release

To determine if some other cause for increased energy availability could be found, hearts from conditioned and sedentary animals were analyzed for glycogen, lipids and high energy phosphates.

Cardiac glycogen: Figure 4 shows the effects of physical training on endogenous cardiac glycogen stores. Cardiac glycogen serves as an endogenous substrate store and reservoir for emergency energy formation. Hearts of conditioned rats had greater endogenous glycogen stores than hearts of sedentary animals. Figure 4 also demonstrates that this glycogen could be mobilized for exercise during a short swim or with the beta adrenergic stimulus of parenterally administered isoproterenol. This modest increase in cardiac glycogen availability would not deliver a great deal of energy but could be important in borderline hypoxic states.

Lipids and high energy phosphates: Endogenous triglycerides are also a potential reservoir for energy formation, and these lipids were slightly decreased in the hearts of conditioned animals.[1,7] Studies of the metabolic conversion of glucose to lactate or carbon dioxide showed no difference between hearts of sedentary and conditioned animals during aerobic conditions, but during hypoxia there was a tendency for greater conversion to lactate in hearts of conditioned animals.[3] Studies of free fatty acid metabolism by conditioned hearts also showed a slight increase in turnover of fatty acid through the triglyceride pool.[3,7] The levels of high energy phosphate stores, creatine phosphate and adenosine triphosphate, were similar in hearts of sedentary and conditioned animals.[1]

Therefore, in terms of metabolism of fatty acids and glucose, the main sources of cardiac energy, and of high energy phosphate stores, there appeared to be no major difference in hearts of physically trained animals and of sedentary animals that could account for the difference in cardiac performance.

Pyruvate kinase and cytochrome oxidase: The question remained whether there were alterations in the pathways of energy liberation. To investigate this possibility, the activity levels of pyruvate kinase, a marker for the glycolytic pathway, and cytochrome oxidase, a marker for the oxidative pathway, were measured in hearts of sedentary and conditioned rats.[8] Cytochrome oxidase levels were not different in the two groups of hearts, whereas pyruvate kinase values were 50 percent higher in hearts of conditioned than in sedentary animals. This finding confirmed the work of Oscai et al.,[9] who demonstrated no increase in oxidative enzymes in hearts of trained animals. Therefore, we concluded that the beneficial effects of physical training probably cannot be attributed to an increase in the capacity of the myocardial cell for aerobic energy formation.

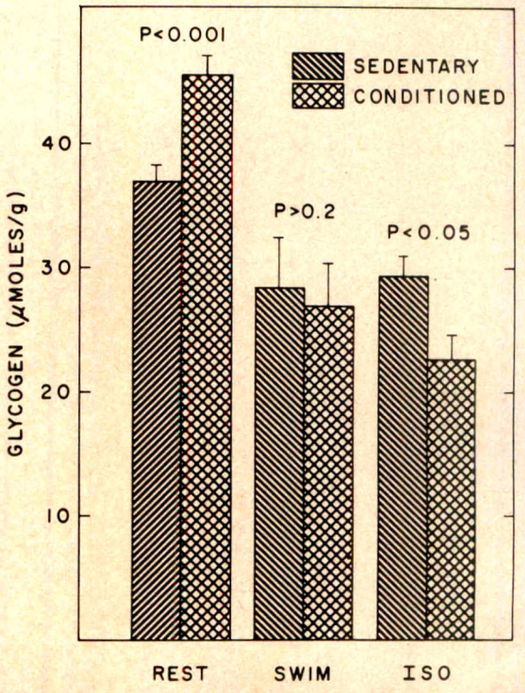

FIGURE 4. Effects of swimming upon myocardial glycogen levels. Values for rest were taken 36 hours after the last swim (conditioned rats). Values for swimming were taken immediately after a 75 minute swim (sedentary and conditioned rats). Values for isoproterenol (ISO) were taken 30 minutes after subcutaneous injection of 50 μg/kg in both groups.

Energy Utilization

Since the studies of the energy production pathways provided evidence for only modest potential increases in energy delivery it became important to investigate some of the mechanisms of energy utilization. For these studies animals swam 90 minutes a day, 5 days a week for periods of 4, 6 and 8 weeks; an additional group swam 75 minutes twice daily for 8 weeks.

Calcium and magnesium ATPase: Figure 5 demonstrates the effects of these swimming programs on the enzymatic capacity to split ATP by actomyosin (ATPase) extracted from hearts of conditioned and sedentary animals.[10] Calcium ATPase studied in the presence of high ionic strength solutions showed increased activity after 6 and 8 weeks of the swimming program. The magnitude of increase was linearly related to the total number of hours that the animals swam. Magnesium ATPase, studied at lower ionic strengths, also increased with the swimming program.

Superprecipitation of actomyosin: Another measurement of actomyosin activity is the rate at which an actomyosin gel superprecipitates in the presence of ATP. Figure 6 shows that the rate of superprecipitation of actomyosin gels was significantly higher in preparations from hearts of conditioned animals than in those from hearts of sedentary animals. The increased actomyosin ATPase activity and the

faster rate of superprecipitation correlate well with the suggested increased contractility of the hearts from conditioned rats as demonstrated in the isolated working perfused heart apparatus.

In these studies of actomyosin the heart weights were the same in control and trained animals except in the group that swam 8 weeks for 150 minutes daily. The conditioned rats in this group had cardiac hypertrophy.[10] Thus, these studies demonstrate an increase in ATPase activity that occurs before the onset of hypertrophy but continues into the hypertrophic phase. This finding is in contrast with the re-

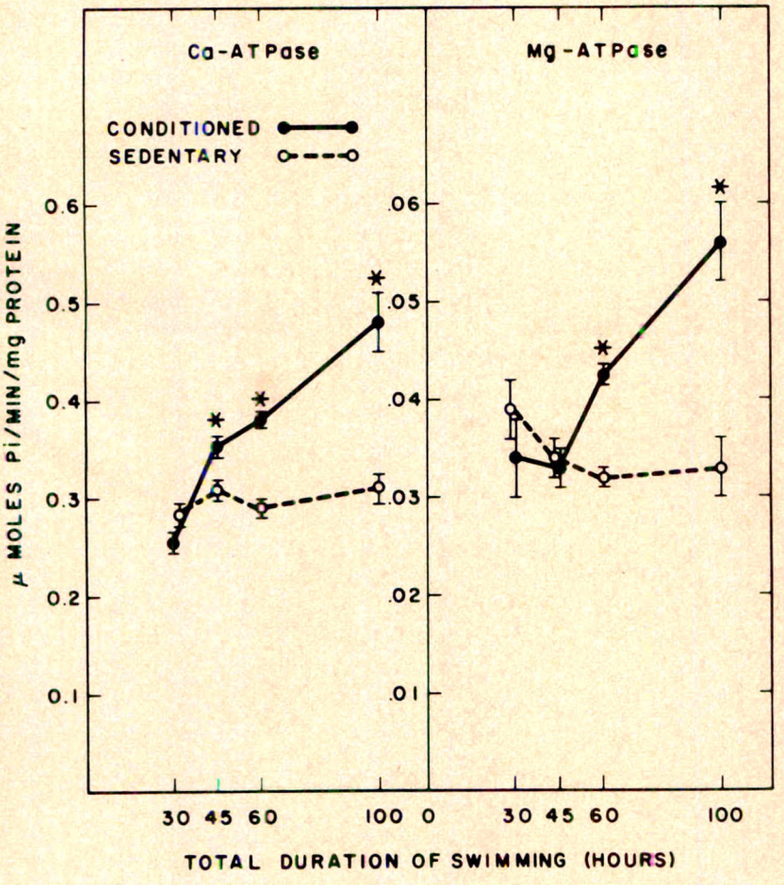

FIGURE 5. Effect of total duration of swimming on calcium (Ca^{++})- and magnesium (Mg^{++})-stimulated ATPase activities of cardiac actomyosin. Data are means ± standard error. **Asterisk** indicates $P < 0.01$ when comparing hearts from control and conditioned animals. 30, 45 and 60 hours represent swimming 90 min/day for 4, 6 and 8 weeks, respectively; 100 hours represents swimming 150 min/day for 8 weeks. Swimming was conducted 5 days/week. (Reproduced by permission from Bhan and Scheuer.[10])

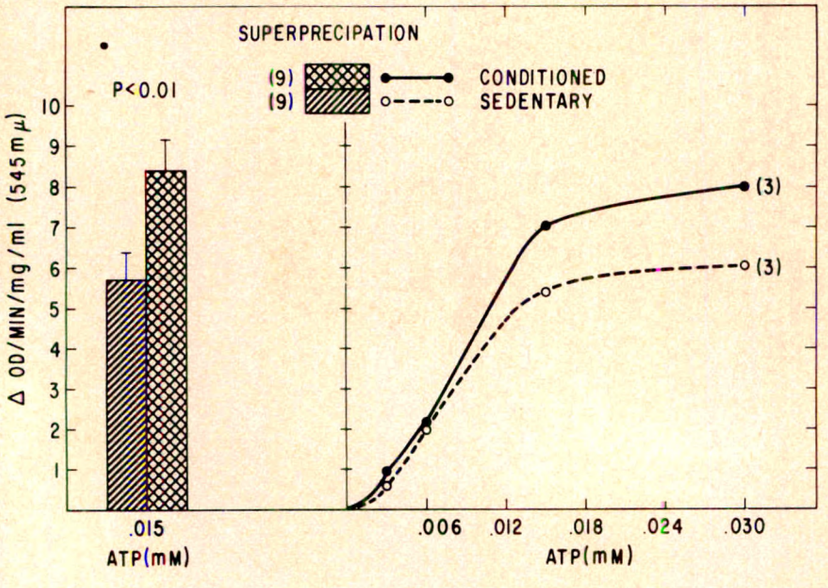

FIGURE 6. Rate of superprecipitation of actomyosin from hearts of conditioned rats. **Curves on right** show rate of superprecipitation (ΔOD/mg per ml per min) as a function of adenosine triphosphate (ATP) concentration. **Bars on left** show mean rates of superprecipitation for nine hearts at 0.0015 millimoles ATP. (Reproduced by permission from Bhan and Scheuer.[10])

duced ATPase activity that accompanies decreased contractility when hearts are made hypertrophic with hemodynamic overload.[11]

Pure myosin ATPase activity: To validate the enzymatic changes in the contractile proteins, pure myosin was isolated from hearts of conditioned rats, and the ATPase activity was studied.[12] Physical training was associated with a 30 percent increase in pure myosin ATPase activity. To elucidate the mechanism of this increased activity, the myosin was reacted with a number of agents that changed the confirmation of the active site of the enzyme. It was demonstrated that ethylene glycol, which disrupts some of the bonds at the active site, had a more powerful effect on myosin from control than from conditioned hearts. Iodoacetamide and 5,5′-dithiobis-(2-nitrobenzoic acid), both agents that bind sulfhydryl groups at the active site, also had a greater effect on myosin from control hearts than from conditioned hearts. These results are consistent with the interpretation that a conformational change at the active site of myosin is induced by physical training in hearts of conditioned rats and is responsible for an alteration in the enzymatic activity. This change appears to be closely related to the availability of sulfhydryl groups at the active site. Therefore, these studies on the energy utilization phase of cardiac metabolism demonstrate a change in the enzymatic activity of the proteins that might be partially responsible for increased cardiac reserve in the hearts of animals that have been conditioned.

Effects of Hypoxia on Function and Metabolism of Conditioned Hearts

Since epidemiologic evidence suggests that one effect of physical training may be to increase the resistance of the heart to myocardial ischemia, but not to prevent the development of atherosclerosis, we[13] conducted further experiments in the isolated heart apparatus to investigate how hearts from conditioned rats respond to hypoxia. The first studies were performed in an apparatus in which the heart beats isovolumically. These demonstrated that hearts of conditioned rats tended to have a smaller increase in end-diastolic pressure than hearts of sedentary rats during hypoxia but that developed left ventricular systolic pressure and maximal dP/dt were not improved by physical training. There were no differences in values for oxygen delivery, lactate production, lactate/pyruvate ratio and accumulation of the reduced form of nicotinamide adenine dinucleotide (NADH), as measured by epicardial fluorimetry during hypoxia in hearts of sedentary and conditioned rats.

Hypoxia and cardiac performance: Figure 7 shows the effect of hypoxia on hearts in the isolated working rat heart apparatus. Here the hearts were perfused first under aerobic conditions at 10 cm atrial pressure and then underwent hypoxic conditions while the atrial pressure remained at 10 cm and was then raised to 20 cm. A recovery period followed during which perfusion conditions were the same as in

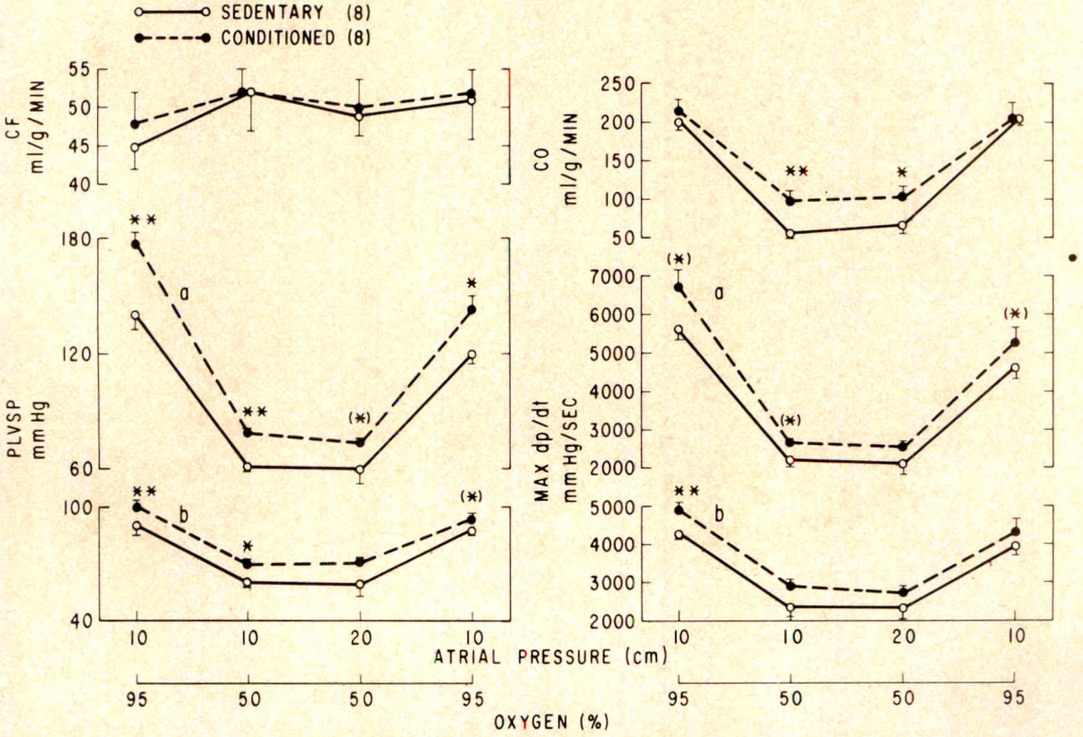

FIGURE 7. Effects of hypoxia on the performance of conditioned hearts in the working rat heart apparatus. Symbols as in Figure 1. (Reproduced from Scheuer and Stezoski[13] by permission of the American Heart Association, Inc.)

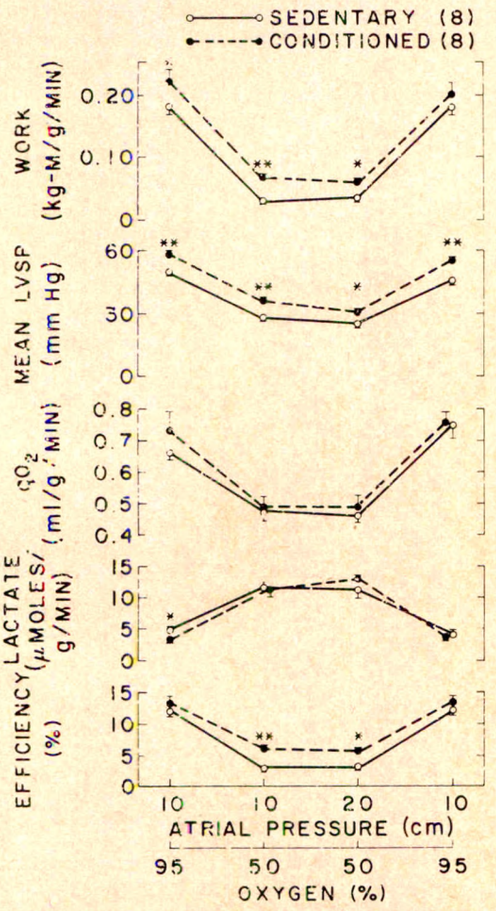

FIGURE 8. Cardiac work and metabolism in conditioned hearts during hypoxia in the working rat heart apparatus. Designations as in Figure 2. Work, qO_2 and lactate output are per gram dry weight. (Reproduced from Scheuer and Stezoski[13] by permission of the American Heart Association, Inc.)

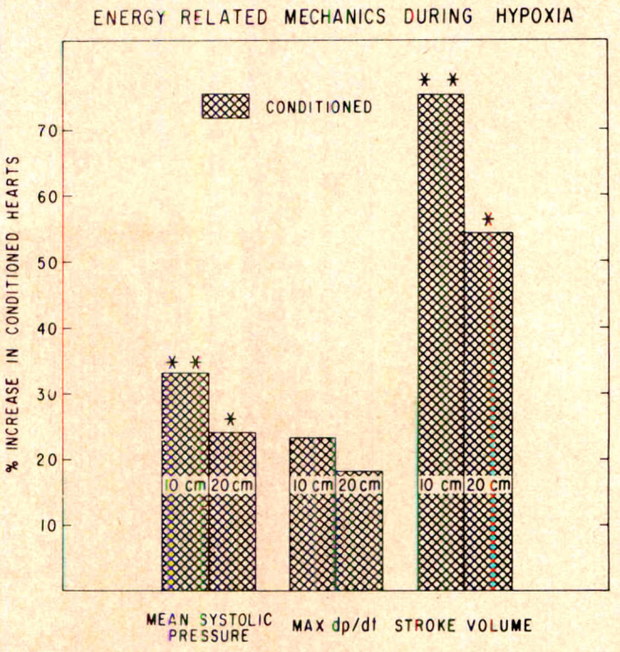

FIGURE 9. Percent increase for conditioned hearts over sedentary hearts in energy-related functions. **Asterisks** indicate statistical significance as in previous figures. Max dp/dt = maximal rate of pressure rise.

the control period. During hypoxia, cardiac output was almost twice as high in hearts of conditioned rats as in those of sedentary control rats. There was a slightly greater left ventricular pressure development but no significant difference during hypoxia in maximal dP/dt. Also the pressure and dP/dt failed to respond to an increase in preload or afterload, indicating that the heart had lost its reserve capacity to respond to stress.

Cardiac work and metabolism during hypoxia: Figure 8 shows the external work and pressure relations in these hearts together with the metabolic findings. External cardiac work was almost twice as great during hypoxia in hearts of conditioned rats as in those of sedentary rats, and mean left ventricular systolic pressure, which relates to wall tension, was only slightly greater during hypoxia in the conditioned rats. There was no difference during hypoxia between the two groups in myocardial oxygen consumption or lactate production values, thus suggesting that energy delivery during hypoxia was the same in hearts of sedentary and conditioned animals. External efficiency was twice as great during hypoxia in hearts of conditioned animals as in hearts of sedentary animals. Thus, hearts of conditioned animals had greater cardiac output, cardiac work and mean pressure performance than hearts of sedentary animals during hypoxia without any evidence of an increase in energy production. High energy phosphate stores and glycogen levels were the same during hypoxia in hearts of conditioned and sedentary rats.[13]

Figure 9 shows the percent increase of performance of hearts of conditioned animals over the control level during hypoxia. There was a 20 to 30 percent greater mean systolic pressure in hearts of conditioned rats during hypoxia but a 55 to 70 percent greater stroke volume. There was no significant difference in maximal dP/dt. When the end-diastolic pressure is the same, as it was in these experiments, mean systolic pressure relates most closely to wall tension, maximal dP/dt correlates with contractility and stroke volume correlates with extent of fiber shortening. These three factors are primary determinants of energy utilization in the myocardium per heartbeat. Tension and contractility are the major determinants of energy consumption, whereas fiber shortening against a load costs very little energy. Therefore, by increasing the stroke volume, and thus its fiber shortening, the conditioned heart would increase its cardiac work efficiently with little change in energy utilization.

Comments

Aerobic performance of hearts of conditioned rats in the working rat heart apparatus was improved as

measured by the responses to rapid pacing and to increased preload or afterload. This improvement was related in part to a greater capacity for increased coronary flow and oxygen delivery to the myocardium.

Hearts from conditioned rats had a slight increase in endogenous glycogen stores, which could be mobilized by stressful stimuli. Triglyceride levels were slightly depressed in hearts of conditioned animals, and levels of high energy phosphate compounds were normal. When studied in the arrested state, conditioned hearts appeared to have a faster turnover of the triglyceride fatty acid pool but no other differences in basal glucose or fatty acid metabolism.

Oxidative enzymes were not increased in hearts of conditioned rats, but actomyosin and myosin ATPase activity levels in these hearts were increased in proportion to the severity and duration of the conditioning process. This increase in ATPase activity was associated with a higher rate of actomyosin superprecipitation.

When studied in the working rat heart apparatus, the performance of hearts of conditioned rats appeared to be relatively resistant to hypoxia. This appeared to be due not to an improvement in energy formation but to more efficient mechanisms of energy utilization.

Many questions remain unanswered by these investigations. In most of the studies hypertrophy of the heart was absent. Therefore, the information may not be relevant to the subject who undergoes an extreme training program and manifests cardiac hypertrophy. It is possible that some training programs may be beneficial and others deleterious to the heart. We do not know the optimal program for promoting cardiac benefits or how the effects of training can be maintained once they have been developed. Finally, the experiments described were performed in young to middle-aged rats with a normal heart. Extrapolation of these in vitro results to intact human subjects who may have cardiac disease must be made with caution.

Medical Screening of Patients with Coronary Artery Disease

Criteria for Entrance into Exercise Conditioning Programs

MALCOLM M. McHENRY, MD, FACC

Davis and Sacramento, California

Although considerable emphasis has been placed on stress testing and physical training of patients with coronary artery disease, data on safe and thorough preliminary medical evaluation are scarce. Because the routine history and physical examination are not sufficient to protect the exercising subject, medical screening attempts a thorough analysis of the patient's motivation, physical status, possible risk factors and the probability of benefit.

Motivation is a critical factor since training for prolonged periods of time at high levels of heart rate and oxygen consumption may be required. Patients who have unstable angina or who may be harmed by increased myocardial oxygen requirements must be excluded. Concomitant influencing diseases and certain medications may also be causes for rejecting a patient. Valvular heart disease and severe systemic hypertension are not associated with benefit from exercise conditioning. The screening physician must exclude patients with certain abnormal electrocardiographic patterns, such as bilateral bundle branch block and type II second degree atrioventricular block, and he must be assured that he is dealing with coronary artery disease, not a pathologic process that mimics it. When these principles are applied, few persons in organized programs of exercise conditioning should suffer, and the yield of good results should be enhanced.

The advent of coronary artery bypass surgery has not eliminated the need for continued medical treatment of patients with coronary artery disease. During the last decade, interest in exercise conditioning programs for such patients has increased because of clinical and experimental evidence of benefit.[1,2] Carefully designed training protocols[3] have been developed to observe, train and record results in such patients. Unfortunately, the majority of exercise programs are unsupervised and frequently undertaken by the patient on his own. As yet, unsupervised training has not resulted in significant mortality. However, the increasing awareness of exercise benefits both to the patient with coronary artery disease and to persons at risk of such disease suggests that the exercise fad itself may eventually become a risk factor.

The nonuniformity of training programs is paralleled by a similar inconsistency in preexercise medical screening. A "good history and physical examination" are not in themselves sufficient to protect the exercising subject.[4] Although these procedures are prerequisites to prevention of complications, they represent a somewhat crude assessment of participant risk. Yet, when they are combined with more subtle assessments, such as exercise stress testing, it is possible to eliminate most unsuitable subjects.

A review of published reports reveals few data on preliminary medical evaluation for stress testing and training. This paper therefore presents guidelines for patient safety and rejection, emphasizing key

aspects of the evaluation and the differences between a routine examination and a medical screening.

Who Should Be Screened?

All patients with known or suspected coronary artery disease deserve careful screening. In addition, all adults of 40 years or over contemplating exercise training should be evaluated, as should persons of any age with potentially complicating illnesses, coronary risk factors or a possible past history of heart disease.

Screening Aims

The screening analysis has three major aims: (1) assessment of motivation, (2) elimination of undue risk, and (3) evaluation of potential benefit. These factors can be investigated by a specific history and physical examination in association with some laboratory procedures.

Motivation

Motivation, often neglected in preexercise evaluation, is a major factor in program adherence and patient safety. Cardiovascular conditioning may be necessary for months to years at levels of activity requiring a high heart rate and oxygen consumption at 65 to 85 percent of the maximal rate. Thus, poorly motivated subjects are frequently training failures. Overly motivated or overly competitive subjects may be dangerous to themselves or to the program. Such persons tend to follow rules and protocol poorly and may challenge the most fit members of the group or exceed their musculoskeletal and cardiorespiratory capacities.[7] The dropout rate of poorly or overly motivated subjects may be high. Motivation is assessed principally thorough a carefully taken history that stresses the patient's personal and social habits.[8] The five principal factors that influence adherence to an exercise program are listed in Table I.

People agreeing to train expect certain rewards. In general, these are positive feelings of health and well-being and the belief that exercise will favorably affect survival and functional capacity. Such feelings encourage program participants to continue even though training may be difficult and time-consuming. In addition, people who are likely to adhere to a program typically enjoy exercise. In many cases they have previously participated in exercise programs or sports and the return to training represents a combination of therapy and relaxation. Lastly, well motivated subjects, although questioning may indicate that they have a competitive personality, have control of their aggressive drives, have a positive attitude toward exercise and are not bored by exercise, realizing that it is therapy, not merely an enforced, meaningless obligation.

The screening physician must also obtain other information that may affect adherence to the program.[9] Does the subject understand the program? Does his working or professional schedule allow it? Can he agree to participation and supervision in a group program in which he will receive data about his performance and his physical safety will be assured? Has he performed well in past programs and adhered realistically to dietary or other measures designed to reduce risk factors? Finally, the reasons for referral of a patient to a training program must be scrutinized. Often a subject is referred only because medical treatment has failed him.

TABLE I

Motivation—Five Factors Influencing Program Adherence

1. Prior history of habitual exercise or participation in sports
2. Competitive personality traits
3. Fear of incapacitation
4. Desire for good health and feeling of well-being
5. Enjoyment of exercise without boredom

TABLE II

Clinical Assessment of Undue Risk

History
1. Increasing angina
2. Duration since myocardial infarction
3. Congestive heart failure or low cardiac output
4. Symptomatic arrhythmias
5. Medication
6. Severe systemic diseases
7. Exertional hypotension or syncope

Physical examination
1. Congestive heart failure
2. Abnormal precordial pulsation or thrill
3. Murmurs consistent with valvular disease
4. Diminished or abnormal arterial pulsations
5. Elevated diastolic blood pressure with retinopathy

Laboratory evaluation
1. Specific abnormal electrocardiographic patterns
2. Chest X-ray abnormalities
3. Abnormal results of blood studies

Undue Risk

The second major aim of screening is to identify and reject patients who could be harmed by an exercise conditioning program. For this purpose, a thorough and total medical evaluation must be made. The assessment must include an incisive review of the patient's history, a careful physical examination and specific laboratory procedures (Table II). Patient safety and program success require that this evaluation, although brief, review both the gross and subtle features of actual or potential disease.

History

From the history, the examiner can determine whether the subject is threatened by inordinate myocardial oxygen requirements, the hemodynamic consequences of medication during training, or other systemic diseases. Patients with coronary artery disease may remain well compensated when metabolic demand and vascular supply are matched. Because

TABLE III

Major Causes for Rejecting Patients

1. Clinically unstable or inadequately treated disease
2. Clinically important complicating illnesses
3. Specific medications
4. Diseases mimicking coronary artery disease
5. Poor motivation

exercise may alter this relation, evidence of inadequate oxygen supply must be sought in the history.

Unstable angina: Although unstable angina is the most common deterrent to training, it is often difficult to identify. Standard questioning may not reveal that the subject who now has pain on moderate effort also has spontaneous ischemic pain, nocturnal pain, an increasing need for nitrites, more prolonged periods of angina or has had to pace himself to a lower level of energy expenditure. This changing anginal pattern may assume many forms. There may be an obvious and severe intensification of ischemic symptoms (crescendo or preinfarction angina), or the signs may be insidious and more slowly progressive. Retrospective analysis of the patterns of pain leading to myocardial infarction frequently shows a slow and gradual intensification of complaints culminating in an acute coronary event. The screening physician must appreciate these subtle changes if he is to ensure that patients with these symptoms do not enter the training program. In patients who are convalescing from a myocardial infarction, myocardial oxygen consumption should not be inordinately augmented until complete healing has occurred. A period of about 3 months is a standard interval for ensuring safety.

Reduced ventricular function and myocardial reserve: Patients with symptomatic congestive heart failure or low cardiac output (weakness on effort, dyspnea, fatigue and malaise) have reduced ventricular function and myocardial reserve. Increasing myocardial oxygen requirements in such patients can only be harmful.[10] The occurrence of symptomatic cardiac arrhythmias increases oxygen demand inappropriately. The arrhythmia must first be identified by type and then treated. All of the aforementioned situations that inappropriately increase myocardial oxygen requirements can be identified by a carefully taken history, then treated and potentially controlled. Upon return to a stable condition, the patient may again be considered for training.

Medications: Certain medications are absolute or relative contraindications to training. Patients with systemic hypertension taking ganglionic blocking agents should be excluded. The hypotension on standing at rest associated with further peripheral vasodilatation on effort may reduce coronary perfusion to a significant degree. A relative contraindication exists with the use of beta adrenergic blocking agents. Although beta adrenergic blockade simulates some of the effects of training (reduced exercising heart rate and decreased myocardial oxygen requirements),[11] it also causes depression of myocardial function.[12] If in fact a significant benefit of training in patients with coronary artery disease is a redistribution of peripheral blood flow to active muscle[13] and a decrease in myocardial oxygen consumption through a reduction in ejection time, heart rate and peripheral resistance,[14] inhibition of myocardial function would not appear to have a salutary effect and might negate other benefits. The use of digitalis, quinidine and other agents that alter the repolarization characteristics of the electrocardiogram could be considered relative contraindications only if the intent of training is in part to observe electrocardiographic improvement or exercise-induced changes in ischemic electrocardiographic thresholds.[15]

Systemic diseases: Several systemic diseases may significantly affect or contraindicate exercise. These include brittle insulin-dependent diabetes mellitus, cerebrovascular and peripheral vascular insufficiency, severe systemic hypertension and pulmonary emphysema when associated with hypoxia, hypercarbia and pulmonary hypertension. Exertional syncope or a history of hypotension also indicates undue risk.

Physical Examination

Careful examination of the cardiovascular system may disclose a patient at risk. Hyperthyroidism, congestive heart failure and abdominal aortic aneurysm are easily identified. A thorough preexercise cardiovascular screening attempts to identify more subtle lesions by particular attention to inspection, palpation of peripheral arteries, palpation and auscultation of the heart and close examination of the eye grounds.

A precordial thrill may indicate an acquired postinfarction ventricular septal defect or papillary muscle dysfunction. An apical impulse may indicate left ventricular hypertrophy or a ventricular aneurysm. A left parasternal impulse may indicate right ventricular hypertrophy of many causes or left atrial hypertension. All these conditions merit further clinical evaluation.

Cardiac auscultation is a critical part of the examination. Murmurs suggestive of acquired or congenital valvular disease must be identified. Patients with aortic stenosis of significant degree tolerate effort poorly, as manifested by exertional syncope and occasionally by sudden death. Similarly, subjects with aortic or mitral insufficiency have not been shown to benefit from training, and their marginal cardiac reserve may be threatened. Training may theoretically benefit patients with mild to moderate mitral valve stenosis.[10] In this lesion, the expected training effect of slowing of the submaximal heart rate and prolongation of diastolic filling period might reduce the end-diastolic mitral gradient. But training is not generally recommended as profitable for subjects with congenital or acquired valvular lesions.

Patients with severe systemic hypertension should be rejected for training. Such hypertension may be defined as a diastolic blood pressure greater than 120

mm Hg accompanied by advanced retinopathy. Although training can reduce diastolic pressure elevations of mild to moderate degree,[16] this reduction would not be expected in more severe hypertension.[17] The effects of exercise on fixed vascular resistance have not been defined clearly enough to exclude significant risk.

Laboratory Examinations

A limited number of laboratory procedures are essential to the careful preexercise screening. These consist basically of a resting electrocardiogram, a chest roentgenogram and blood chemistry determinations with special attention given to blood sugar, electrolytes and myocardial enzymes.

Electrocardiogram: Analysis of the electrocardiogram is probably the most important laboratory procedure. Evidence of increasing ischemia, unsuspected or clinically undetected infarction and specific arrhythmias and conduction disturbances contraindicate entrance into training. Ventricular arrhythmias, particularly multifocal premature ventricular beats, require delay of training and prompt treatment. Conduction disturbances such as complete right bundle branch block and left bundle branch block produce only insignificant hemodynamic changes in subjects without major coronary artery disease.[18–20] However, the occurrence of bundle branch block in acute infarction increases mortality[21,22] and is indicative of extensive myocardial damage. Therefore, the combination of bundle branch block and coronary artery disease indicates an added risk or contraindication to training.

Two specific conduction disturbances merit discussion because of their potentially lethal consequences during exercise. They are type II (Mobitz) second degree atrioventricular block and bilateral bundle branch block. In both, destructive infranodal lesions are assumed.[23–25] With exercise, the normally expected shortening of atrioventricular refractoriness does not occur and the accelerated atrial rate finds ventricular unresponsiveness.[26] Complete heart block has been documented on occasion when such rate increases occur,[27] and bilateral bundle branch block appears to be the most common electrophysiologic mechanism of complete heart block.[28]

Roentgenogram: X-ray examination of the chest for heart size represents another simple technique for identifying a subject with reduced cardiac reserve. Cardiomegaly of any cause requires investigation and may indicate extensive myocardial damage. The identification on X-ray or fluoroscopic study of coronary arterial calcification has been correlated angiographically and pathologically with severe atherosclerotic obstruction[29] and may indicate undue training risk.

Patient Benefit

The final screening analysis is concerned with the assurance of patient benefit. One can assume that benefit will occur if the subject has met the motivational, historical, clinical and laboratory standards described. However, training benefit is restricted to subjects with coronary artery disease; exercise programs in other forms of heart disease are both untested and potentially harmful. Therefore, the precise nature of the disease process causing ischemic pain must be known.

Patients may have angina pectoris without having coronary artery disease. This is dramatically seen in severe valvular aortic stenosis, idiopathic hypertrophic subaortic stenosis, other forms of cardiomyopathy and severe pulmonary hypertension, especially that due to mitral stenosis or occurring with congenital heart disease. Training programs in these conditions are not beneficial and may be lethal.

Conclusions

When thoughtful and carefully performed screening procedures are applied, few patients in organized training protocols will suffer. When basic guidelines for patient rejection are followed (Table III), risk is minimized, the subject is protected and the yield of good results should be enhanced.

There can be no substitute for adequate medical control and management of patients with coronary artery disease. These measures include treatment of increasing angina, control of the symptoms of heart failure and low cardiac output and treatment of coexisting systemic diseases. Before a patient enters a training program, his medications must be reviewed to ensure that their effects will not be reversed by exercise, and diseases producing ischemic pain and mimicking arteriosclerotic heart disease must be excluded. Finally, the patient must be properly motivated.

Individual Exercise Prescription

JACK H. WILMORE, PhD

Davis, California

The ability to prescribe exercise for both normal persons and patients with heart disease has advanced from an art to a science during the past decade. Research during this period has given the physician and the exercise physiologist the capability of designing exercise programs to meet a specific person's individual needs, interests and capacity. In such programs, participants first undergo a thorough medical evaluation, including a detailed personal health and family history, physical examination, a resting 12 lead electrocardiogram and an exercise electrocardiogram. Either as part of the exercise electrocardiographic evaluation or as a separate exercise test, individual work capacity (either actual or estimated maximal oxygen uptake) and the maximal heart rate are determined.

In the actual exercise prescription, attention is given to four factors: (1) type of activity, (2) frequency of participation, (3) duration of each exercise period, and (4) intensity of the effort. To promote and maintain basic cardiorespiratory health and endurance, the exercise must be of an endurance nature—walk-jog-run, hiking, swimming or bicycling. It should be performed at least three times a week for 20 to 30 minutes at each session. Significant changes in work capacity and cardiovascular function occur when a person exercises at a level as low as 60 percent of his working capacity. A level of 60 to 75 percent is normally used to initiate an exercise prescription. This level can be easily monitored by the participant, using 60 to 75 percent of his maximal heart rate as the guide for his training or exercising heart rate. In all cases, the exercise is programmed to fit the individual subject, not vice versa, as often happens in group programs. This approach provides a safe and efficient means for assisting adults to gain maximal benefit from exercise.

The need to overcome effectively the sedentary habits of our adult population has been recognized for years. Physical inactivity has been intimately associated with obesity, premature cardiovascular disease, unnecessary orthopedic problems, anxiety and emotional tension. The man of today who is 40 years of age or older is definitely at greater risk of having the basic chronic degenerative diseases than his counterpart of 20 years ago. A part of this increased risk can be attributed to the basic inactivity of man today compared with man of that time.

Education and Motivation

Appreciating the need for increased physical activity and translating this need into action are, unfortunately, unrelated events. Any successful exercise program must therefore accomplish two major goals: (1) teach people why they should be physically active, and (2) motivate them to follow through with a personal activity program. The majority of existing exercise programs are short on education.

People are told that they *must* exercise but are given little if any information on *why* they should exercise. The average person today has a relatively sophisticated knowledge of the basic biological sciences and medicine. If he thoroughly understands the reasons for following a routine program of physical activity, he will be more inclined to do so. Probably the most valuable contribution made by Cooper[1] in his initial book Aerobics was to inform an educated audience specifically why exercise is essential to improving and maintaining health.

In addition to educating people, it is necessary to motivate them to act. Initially, much of this motivation can be in the form of external goals and rewards, but once a person has been actively exercising for several months or more, more subtle forms of internal motivation are needed. The individual man or woman must recognize that an exercise program is a lifetime pursuit and not an activity of 3 to 6 months' duration with residual effects that last forever.

Group programs provide excellent opportunities for motivation, teaching and interaction. The influence of the group and its leader or leaders has tremendous motivational significance. Unfortunately, group programs now involve a very small percent of our total adult population. Many people can't or won't take advantage of existing programs often for valid reasons. These people can be helped to develop their own personal exercise program. The remainder of this paper outlines the practical fundamentals of individualized exercise prescription for persons participating in organized groups or in programs designed specifically for them. The reader is referred to Pollock,[2] or Wilmore and Haskell[3] for a more extensive review of the theoretical aspects of exercise prescription.

Exercise Prescription

An individualized exercise prescription provides a practical answer to several problems. Most individual exercise programs are self-designed; that is, a man or woman selects an activity and begins exercising. This is a potentially dangerous practice since most people do not recognize their limitations and are likely to exceed a safe level of exercise. Just as important, people are likely to initiate an activity program without proper medical evaluation. A substantial number of persons have potential symptoms of cardiovascular disease—angina pectoris, for example—make a self-diagnosis, and with a fear of the physician confirming their diagnosis, embark on their own exercise program in an attempt to remedy the situation. Group programs also have associated problems. Although a medical examination may be required for participation in these programs, the exercise is usually prescribed on a mass basis and little or no recognition is given to individual differences: Everyone is expected to do exactly the same thing. The individualized prescription of exercise avoids these hazards. The participant receives medical clearance, his interests and physiologic capacity are individually determined, thus ensuring accurate prescription of an appropriate exercise regimen.

Medical screening: The first step in developing an individualized exercise prescription is to obtain proper medical evaluation.[4] The assessment should be based on a resting 12 lead electrocardiogram, a resting blood pressure determination, a blood lipid profile, a medical history providing pertinent information on past medical problems and familial traits, and a comprehensive physical examination performed by a physician with an understanding of the exercise sciences. Providing there are no contraindications, the participant is then cleared for the exercise test.

Exercise testing: The primary purpose of the exercise test is to determine the normality of the exercise electrocardiogram. In addition, measurements are made of the subject's ventilation, oxygen uptake, blood pressure and heart rate response to the exer-

cise. The work load is increased gradually until the subject reaches the point of fatigue or until clinical symptoms or electrocardiographic abnormalities appear that contraindicate continuation of the test. The plateau of oxygen uptake with an increasing work load indicates the attainment of the subject's maximal oxygen uptake or his physical working capacity. When equipment is not available to assess oxygen uptake, it can be estimated from the length of time of the exercise test. McDonough et al.[5] and Wilmore[6] have found correlations of 0.85 and 0.87, respectively, between maximal oxygen uptake and test duration in men, and Profant et al.[7] reported a correlation of 0.77 in women. The level of maximal oxygen uptake and the normality of the exercise response are the principal factors in the exercise prescription.

Body composition assessment: One additional component which is not essential for the prescription of exercise, but provides important medical and motivational data is the assessment of body composition. With use of either the hydrostatic weighing or the anthropometric estimate technique, lean body weight, relative and absolute body fat and ideal body weight can be estimated with a moderately high degree of accuracy. This assessment accurately identifies obesity, but, equally important, may motivate a participant to adhere to a prescribed dietary and exercise program.

Individualized prescription for exercise program: The actual prescription of exercise is given in an individual consultation immediately after the medical and physiologic evaluation. The prescription is based on: (1) the recommendation from the physician relative to the absence or presence of contraindicative medical problems; (2) a questionnaire on physical activity interests and habits; (3) results of the medical examination; and (4) results of the exercise test, including the actual or estimated maximal oxygen uptake. During the consultation, the results of the exercise stress test and the analysis of body composition are covered in detail. A personally tailored exercise program is then prescribed with attention being given to: (1) the type of activity; (2) the frequency of participation; (3) the duration of each workout; and (4) the intensity at which the activity is to be performed. Generally, an endurance type of activity of particular interest to the participant is suggested. The activity is to be performed three to four times a week for 20 to 30 minutes a day. The subject uses his pulse rate response to the exercise to control the intensity of his performance. He is told to exercise at a heart rate that represents 75 percent of his maximal oxygen uptake. This rate, termed the training heart rate, is well within his capability yet has been demonstrated to exceed the threshold necessary to elicit a training or conditioning response. This procedure applies, of course, only to persons who have no symptoms of heart disease. The training heart rate must be established individually. Use of a standard heart rate such as 150 beats/min for groups of persons all ages is a questionable procedure. This heart rate represents 75 percent of the capacity of the 25 year old but 98 percent of the capacity of the 65 year old and is independent of training state.[2]

The medical and physiologic evaluation and consultation are used as educational experiences. The subject receives explanations of most of the testing procedures and both written and verbal interpretations of his own test results. In addition, he should receive educational materials during the consultation and at various times throughout the year. Participants should also be given specific goals to reach within a specified time period. For example, a subject may be asked to increase his maximal oxygen uptake from 24 to 31 ml/kg per min and decrease his relative fat from 27.5 to 22.5 percent within 6 months. Additional long-range goals are also provided. Participants should be encouraged to return after 6 to 12 months for reevaluation. This procedure, intended to assess the success of the prescription, is also a valuable motivational tool for maintaining participants in an exercise program for the intervening 6 to 12 month period.

Results: The results from two programs using this approach to exercise prescription are presented in Tables I and II. The data in Table I represent changes after a 3 month exercise program and those in Table II after a 6 month program. In both cases, the changes are substantial and are all in the direction of improving the subjects' health profile. However, the changes in body composition and blood lipid levels cannot be attributed solely to the exercise program: many of the participants were also consuming modified diets prescribed by a dietician.

In summary, an individualized approach to the prescription of exercise has been shown to be both feasible and acceptable to the public. Programs based on this approach appear to provide meaningful changes in health. The two key factors in ensuring the success of an individualized program appear to be (1) provision of adequate education, and (2) generation of the motivation needed to carry out the immediate program with an appreciation that exercise is a lifetime pursuit.

Effects of Physical Training on Coronary Risk Factors

JOSEPH A. BONANNO, MD, FACC
JAMES E. LIES, MD

Davis, California

The effects of exercise training on the known coronary risk factors were studied as an isolated intervention in 39 middle-aged men who were at high risk of coronary artery disease. They were separated into two groups of 20 exercising and 19 control subjects who were carefully matched with respect to age, occupation, coronary risk factors and physical fitness. The exercising subjects participated in a 12 week, supervised training program, but no other attempt to reduce risk factors was made in either group.

Exercise training led to a substantial improvement in the physical fitness as determined by increased maximal oxygen uptake, oxygen pulse, ventilation and physical work capacity. Furthermore, there was a significant reduction of systolic blood pressure in the hypertensive subjects who exercised (from 148 to 135 mm Hg, $P < 0.01$) but not in the hypertensive control subjects (from 150 to 147 mm Hg); the diastolic pressure decreased in both groups. Hypertriglyceridemia also decreased in response to exercise, but there was no significant change in cholesterol levels, obesity, cigarette smoking or psychological profile. A physical training program is therefore valuable as adjunctive therapy in patients at high risk of coronary disease who have hypertension or hypertriglyceridemia.

Numerous reports over the past 20 years have drawn attention to the relation between physical inactivity and coronary artery disease. As a result, physical training programs have been widely advocated, and it has been inferred that participation in such programs would reduce the risk of and protect against coronary disease. This inference has been drawn primarily from two sets of observations: (1) epidemiologic studies showing that persons with more physically demanding occupations or leisure time activities generally have a lower rate of coronary artery disease than those who are more sedentary,[1–3] and (2) studies showing that the cardiovascular functional capacity of patients with coronary artery disease can be dramatically improved by physical training programs.[4–10] However, the role of physical training in the primary prevention of coronary disease or reduction of the mortality and morbidity from this disease has never been demonstrated.

Since coronary artery disease is caused by many factors, it is difficult to assess the individual impact or contribution of any single factor. This difficulty is further compounded when one attempts to assess the results of an intervention directed against that factor. But inferential evidence supporting the role of exercise training in primary prevention can be derived by the demonstration of a favorable influence on the major coronary risk factors. Thus, many authors have investigated the effects of training on serum lipids,[10–13] hypertension,[14–17] obesity[10,13] and psychological profile.[1,4,10,18] The reported

results have varied and are often difficult to compare because the studies have been uncontrolled or several interventions were used concomitantly. Accordingly, a carefully matched and controlled study was undertaken to determine the effects of exercise intervention as an independent variable on hypertension, hyperlipidemia, obesity and cigarette smoking in a group of subjects at high risk of coronary artery disease.

Methods

Subjects. Forty untreated male volunteers with multiple coronary risk factors were identified from a heart disease screening program of policemen, firemen and sheriff's deputies in Sacramento. All underwent a complete physical examination with resting electrocardiogram, chest roentgenograms (posteroanterior and lateral views), maximal progressive treadmill stress tests with "on line" respiratory gas analysis, and a series of blood chemistry analyses. They were then separated into exercise and control groups which were closely matched with respect to age, occupation, coronary risk factors (hypertension, hyperlipidemia, obesity, cigarette smoking) and physical fitness (Table I).

The exercise group participated in a supervised physical training program, but no other effort to reduce risk factors was made during the course of this study. All subjects were specifically instructed to avoid alterations of diet and treatment of hypertension, and no attempt was made to have them discontinue cigarette smoking. In addition, the control group was asked to refrain from increasing their usual physical activities.

Blood pressure measurements: The blood pressure was recorded from both arms (at heart level) with a standard size cuff and mercury manometer while the subjects were seated. The arm with the highest pressure was used for subsequent blood pressure measurement, and at least three recordings, separated by more than 5 minutes, were taken during each of three examinations made before the start of the training program. The "pretraining" blood pressure was taken as the average of the three lowest readings during the third examination. All subjects in both groups had their blood pressure recorded in a similar manner at the midpoint and termination of the training program. All recordings were made by the same two physicians.

Lipid measurements: Serum cholesterol (automated method[19]) and triglyceride determinations (enzymatic method[20]) were obtained after a 14 hour overnight fast at the beginning and end of the training program. All of these measurements were carried out in duplicate by the same technician in the Lipid Laboratory of the University of California at Davis-Sacramento Medical Center.

Cardiovascular function capacity: Progressive multistage treadmill stress tests were carried out to the voluntary maximum using a standard protocol at the beginning, midpoint and conclusion of the training program. "On line" respiratory gas analysis (oxygen, carbon dioxide), ventilation (liters/min) and heart rate were measured every 15 seconds and strip chart recordings of the electrocardiogram were obtained at 1 minute intervals.

Psychological profile: A series of standard psychological tests, including a body image index[21] and adjective checklists that provide a personality profile and depression scale, were administered to all subjects at the beginning and end of the study.

Training program: The training program consisted of three exercise sessions (40 to 55 minutes each) per week (Monday, Wednesday, Friday) for 12 consecutive weeks. All sessions were conducted between 8 and 10 AM and were considered "regular duty." If a training session occurred on an "off duty" day, subjects were compensated for travel and training time at 1 1/2 times their hourly wage.

Each training session began with a 5 to 10 minute "warm up" period of light calisthenics and stretching exercises. This was followed by a 30 to 35 minute individualized period of walk-jog sequences during which the heart rate was maintained at a training level (70 to 85 percent of maximal rate), and this in turn was followed by a 5 to 10 minute "cooling off" period. The exercise sequences were paced by two physical educators, and two physicians carried out

pulse rate and telemetric heart rate monitoring during the training periods. The exercise prescription was steadily increased as necessary to achieve the training heart rate during the program.

Results

Adherence: Thirty-nine of the original 40 subjects completed the study. One of the control subjects moved away from the area during this program and his data were deleted from the study. In the exercise group, 16 subjects (80 percent) attended more than 75 percent of the training sessions; the remaining 4 were present 60 to 75 percent of the time.

Physical fitness: Table II compares variables of cardiopulmonary fitness in the exercise and control groups before and after the training program. The exercise group had a significant reduction in their maximal heart rate and significant increases in their physical work capacity (treadmill duration), maximal oxygen consumption, oxygen pulse (maximal oxygen consumption/heart rate) and ventilation after training. The control group had no significant change in any of these measurements.

Blood pressure: Table III shows the changes in blood pressure in normotensive and hypertensive subjects. After the training program, normotensive and hypertensive subjects in both groups demonstrated a reduction in mean diastolic pressure. The reduction was statistically significant ($P < 0.01$) and similar in magnitude in hypertensive patients in the exercise and control groups. Systolic pressure was significantly reduced ($P < 0.01$) only in the hypertensive subjects who exercised.

Serum lipids: Serum cholesterol and triglyceride levels before and after the training program are shown in Table IV. There were no significant differences in cholesterol values within or between the groups. Triglycerides were significantly reduced in the exercise group when measured 24 hours after an exercise session but returned to base-line levels 96 hours after exercise.

Obesity, cigarette smoking and psychological profile: Although some subjects in both the control and exercise groups appreciably changed in weight during the course of the study, there were no significant differences in the mean weight of either group. No subject in either group discontinued or substantially decreased cigarette smoking during the program. Although all of the subjects who exercised claimed that they "felt better" after the training program, the psychological tests failed to demonstrate improvement in or differences between the groups.

Discussion

Our study demonstrates that a substantial improvement in cardiovascular and pulmonary functional capacity can be achieved by middle-aged, hypertensive, obese, hyperlipidemic, cigarette-smoking men engaged in a properly designed physical training program. This is shown by the significant increases in maximal oxygen consumption, oxygen pulse and ventilation and the concomitant increase in external work capacity (treadmill duration) associated with training. Furthermore, all levels of external work were carried out at a lower heart rate and rate-pressure product after training. The respiratory quotient (Table II) substantiates the fact that a maximal effort was made by the exercise and control groups during both testing periods; thus, differences between the groups cannot be attributed to motivation in the performance of a "voluntary maximum" stress test.[22] These results are in agreement with data from similar studies involving normal subjects and patients with coronary artery disease.[4–11]

Blood pressure: A most important finding was the demonstration of a significant reduction in the blood pressure of hypertensive subjects after exercise train-

ing (Table III). Although several authors[16,23] have shown that the blood pressure response to a given work load is less after training, the effects of training on resting blood pressure have been controversial. Although some investigators[14,15] claim that training has a salutary effect on hypertension, others[17,24] deny any significant change. However, these studies can all be faulted for the lack of an adequate control group, failure to segregate hypertensive from normotensive subjects or the associated use of other therapeutic interventions. Our normotensive subjects had mild decreases in diastolic pressure that were not statistically significant, a finding that is in agreement with other reported data. Hypertensive subjects in both the control and exercise groups had a significant reduction of diastolic pressure; thus, the observed diastolic changes in the latter group cannot be attributed directly to training. These changes may be the result of a reduction in anxiety associated with frequent contacts with the examiner and increasing familiarity during the course of the study.

Systolic blood pressure was significantly reduced only in the hypertensive patients who exercised. The mechanisms underlying this change are obscure. There is evidence that training results in decreased sympathetic tone and peripheral resistance in response to a given exercise stress,[23,25,26] and this also may be true for resting subjects. Whatever the mechanism, a substantial reduction of blood pressure was achieved in these hypertensive subjects in the absence of any other form of hypertensive therapy (drugs, sodium restriction or weight reduction).

Triglycerides and cholesterol: The serum triglycerides were substantially reduced when measured 24 hours after an exercise session but had returned to base-line levels when rechecked 96 hours after exercise. These results are in agreement with those of many published studies. Exercise as an isolated intervention (independent of diet) is an effective means of reducing serum triglycerides, but its effects are short-lived. Approximately three exercise sessions a week would be necessary to maintain the triglyceride reduction although it is obvious that dietary control should also be employed.

The reported effects of training programs on serum cholesterol values have varied.[10–13] However, most studies indicate little or no change in cholesterol in the absence of dietary fat restriction or significant weight loss. If one considers only the base-line and midpoint values (after 6 weeks of training) for cholesterol, both the exercise and control groups demonstrated a "reduction," whereas neither group showed a statistically significant change after 12 weeks. These results underscore the problem of day to day cholesterol variability and the need for multiple determinations in any study of cholesterol changes.

The lack of a significant weight reduction in the exercising subjects is not surprising since we specifically recommended that they not change their dietary habits during this program. Most other studies that have not imposed this restriction have found minor weight reduction or an increase in lean body mass, or both. Our groups had no changes in mean values for lean body mass as determined by skin-fold thickness measurements.

Although our exercising subjects were uniformly enthusiastic over their improved physical prowess during this program, no one was sufficiently motivated to reduce cigarette consumption. It was surprising that there was no demonstrable improvement in the psychological profile of our exercise group since these subjects all claimed that they "felt better" and were proud of their improvements in physical performance. The lack of measureable improvement in results of adjective checklists and body image indexes may be a function of our group selection. All subjects were either law enforcement officers or firefighters who might be expected to be less likely than other groups to acknowledge initially a poor body image or emotional insecurity.

In summary, exercise training improves cardiovascular functional capacity in subjects at high coronary risk and favorably influences hypertension and hypertriglyceridemia but has no appreciable effect on the other coronary risk factors evaluated here. A program of regular exercise is therefore a valuable form of adjunctive therapy in patients at high coronary risk who have hypertension or hypertriglyceridemia. It has not been established that such a program will in fact prevent or reduce the risk of developing coronary artery disease, but that would be a logical inference from the available data.

Long-Term Physiologic Adaptations to Exercise with Special Reference to Performance and Cardiorespiratory Function in Health and Disease

WILLIAM C. ADAMS, PhD
MALCOLM M. McHENRY, MD, FACC
EDMUND M. BERNAUER, Ph. D

Davis, California

The exercise training principles of specificity, overload, individual differences and transiency are discussed and examples of each presented. Disadvantages of the cross-sectional method, and the values of the longitudinal method of ascertaining physical training effects are discussed. The effects of endurance-oriented exercise programs on middle-aged sedentary normal men and patients with coronary artery disease, emphasizing body composition and cardiorespiratory function and basic hemodynamic response to submaximal and maximal exercise, are reviewed. An original study of the effects of endurance-oriented training on patients after myocardial infarction and coronary artery bypass is presented. Emphasis is placed on cardiorespiratory function at submaximal and maximal exercise loads, and the patients' response is contrasted to that of a group of sedentary normal subjects of similar age.

It is concluded that after infarction most trained patients can achieve the performance levels of sedentary normal subjects but that their response to training is often restricted, presumably because residual disease effects myocardial dysfunction. Successful coronary artery bypass surgery seldom normalizes work performance and cardiorespiratory function although it may ameliorate symptoms. Physical training in conjunction with bypass surgery effects a further improvement in work performance and aerobic power.

The long-term effects of systematic physical exercise have been subjected to scientific investigation for at least 60 years. The first comprehensive review was completed by Steinhaus in 1933[1]; more recent discussions are included in exercise physiology textbooks, the most complete being that by Åstrand and Rodahl.[2]

Participation in properly designed exercise training programs increases capacity for muscular work by effecting morphologic and functional changes. These include (1) increased muscular strength and endurance, primarily as a result of enlargement of existing muscle fibers and an increase in the number of capillaries; (2) better neuromuscular coordination, which reduces the energy requirement; (3) altered body composition, generally involving an increase in muscle mass and a decrease in adipose tissue; and (4) increased maximal oxygen uptake, due primarily to increases in blood volume, total hemoglobin, heart size and stroke volume, and a widened arteriovenous oxygen difference. The effects of training on other body systems, and their relative importance to increased physical performance, are not well known.

Until recently, the effects of physical training were frequently attributed to differences between athletes and nonathletes. This suppo-

sition is not entirely valid since athletes are genetically endowed according to the particular requisites of their sport[3] and the distinction between constitutional dissimilarities and the effects of physical training is not amenable to definitive analysis. Primarily for this reason it is preferable to use the longitudinal approach, in which subjects are followed up over an appropriate period of time. Although this method is not without objections from a scientific viewpoint,[2] with proper attention to subject sampling procedures, insistence on stable habitual life patterns during the investigation, motivation, careful monitoring of the intensity of the training program, and appropriate control groups, it is preferred. It has been demonstrated, however, in numerous epidemiologic, cross-sectional investigations that physically active men are less likely to have myocardial infarcts, and when they do, are less apt to die.[4] Although these studies have inherent weaknesses in design, they have provided impetus for the longitudinal investigation of exercise programs on work performance and physiologic variables related to coronary artery disease risk factors in middle-aged normal subjects. Within this context, the effects of physical training on work performance and cardiorespiratory function in health and disease are reviewed.

Principles of Physiologic Adaptation to Training

Specificity of training: Exercise training programs can be biased to achieve particular physiologic effects. Obviously, the effects of a weight training regimen are quite different from those achieved by gradually intensified jogging. But even within a particular activity, there are specific effects. For example, Clausen and Trap-Jensen[5] trained two groups to perform dynamic work on a bicycle ergometer, one group using the arms only and one using leg work only. The reduction in heart rate obtained by training the arm muscles only could not be transferred to an ergometer leg work task, and vice versa. Thus, it was concluded that local changes in the trained muscles are of importance for the effect of training on heart rate. A recent study[6] of female twins with a similar level of maximal oxygen uptake demonstrated that the twin who had continued to engage in competitive freestyle swimming training used a much greater percentage of her maximal oxygen uptake and sustained a significantly faster swimming pace than the twin who had remained active but had given up swimming training 3 years previously. The difference in maximal oxygen uptake was less pronounced in arm ergometer work, and it was concluded that the continued swimming training had, by unknown mechanisms, enabled one twin to achieve close adaptation of central and peripheral functions to the specific work of swimming.

Proper training may increase the size and, some evidence suggests, the number of myofibrils within a muscle fiber. This appears to be primarily the result of a strength training stimulus that affects particularly the white fibers. Utilization of a high resistance, low repetition training program in lifting weights is the most effective method for increasing muscle size and strength. On the other hand, utilization of a low resistance, high repetition program produces an endurance training stimulus that increases the number of capillaries, muscle mitochondria, energy-liberating enzymes in the sarcoplasm and electron transport capacity.[7]

Improved efficiency in terms of reduced energy expenditure is another training effect specific to the particular activity engaged in. Brouha's studies[8] indicate that through training and practice in activities requiring mastery of skills (such as skiing and swimming), energy expenditure is reduced by (1) elimination of unnecessary dynamic and static muscular contractions, (2) more complete relaxation of muscular antagonists, and (3) replacement of voluntary movement with reflex action. In activities that are uncomplicated technically, such as walking, there is no noticeable increase in efficiency as reflected by reduced oxygen consumption.

Overload: Both intensity and duration are important factors influencing the degree of training effect. Depending on the particular requirements of their sport or event, athletes generally use maximal or near-maximal efforts at appropriate rates and duration to enhance the rapid achievement of specific training effects.[7] However, when training middle-aged men, one is more concerned with the training threshold in achieving an optimal intensity. Karvonen[9] demonstrated a reduction in both work and resting heart rates when previously untrained medical students ran on a treadmill for 30 minutes 4 to 5 days per week with speed adjusted to attain a heart rate at 60 percent of the difference between the maximal and resting rates. At lower rates, the training effect was not seen and the speed of running had to be increased for further improvement. The combined effect of intensity and duration may be observed in Figure 1. Initially, a rather rapid decrease in blood lactate was effected, but was followed by a leveling

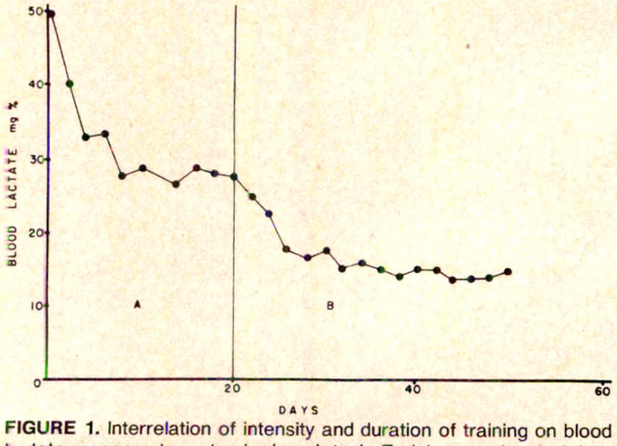

FIGURE 1. Interrelation of intensity and duration of training on blood lactate response to a standard work task. Training consisted of daily running on the treadmill for 20 minutes at 7 miles/hour for 20 days, followed by 15 minutes at 8.5 miles/hour for 30 days. (Reproduced by permission from Brouha.[8])

off after 20 days until the training speed was increased to 8.5 miles/hour, and a further progressive decrease occurred for 10 days before again leveling off.[8]

In the training of middle-aged men, Siegel and coworkers[10] postulate that the number of sessions a week, the total duration of training, the effective duration of each session and the intensity of exercise influence the degree of improvement. They found that training at an intensity necessitating a heart rate slightly in excess of 80 percent of predicted maximal rate, performed 2.6 times a week for an effective total of 30 minutes a week for 15 weeks, resulted in a significant increase in maximal oxygen uptake. The improvement was not maintained by continuing training for 10 effective minutes 0.9 sessions a week.

Individual differences: The response of a subject to a training stimulus is affected by his genetic potential, age and level of physical activity immediately before training. An inverse relation between the initial level of maximal oxygen uptake and percent improvement is shown in Figure 2.[11] Despite their relatively lower initial values, middle-aged men appear to be less trainable than younger subjects. The importance of the pretraining activity level is strikingly portrayed in Figure 3.[12] In three previously sedentary subjects, maximal oxygen uptake increased from an initial value of 2.52 to 3.41 liters/min (35 percent) with 55 days of hard aerobic training, whereas in the two previously active subjects it increased from 4.48 to 4.65 liters/min (4 percent). However, starting with the bed rest value after 21 days, the increases were

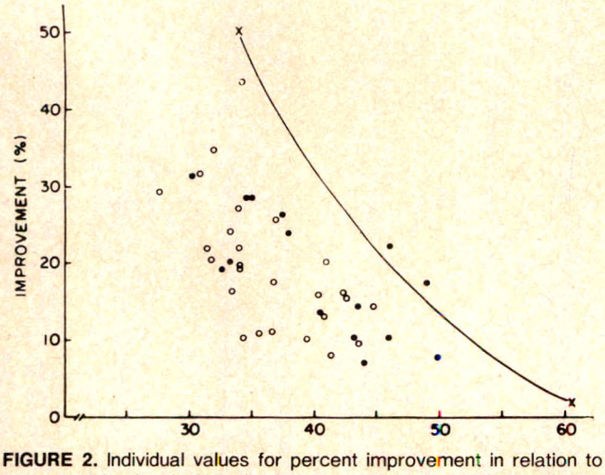

FIGURE 2. Individual values for percent improvement in relation to the pretraining level of maximal oxygen uptake in middle-aged men; the mean value for young men is included as a line. (Reproduced by permission from Saltin.[11])

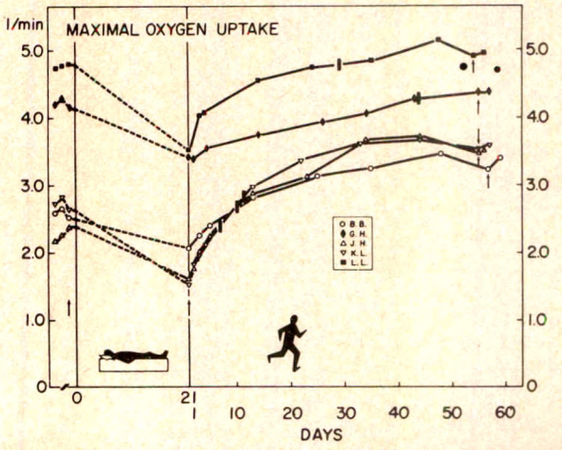

FIGURE 3. Changes in maximal oxygen uptake with bed rest and training. The **heavy bars** indicate the time during the training period at which the maximal oxygen uptake had returned to the control value before bed rest. Subjects G.H. and L. L. were in a trained state at the initiation of the experiment. (Reproduced by permission from Saltin et al.[12])

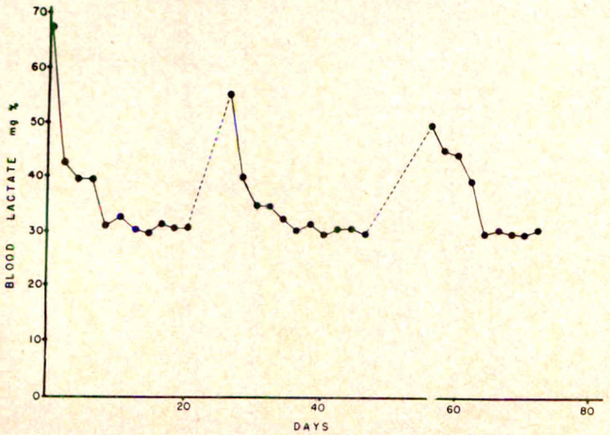

FIGURE 4. Effect of stopping exercise for a few days during a training period on blood lactate response to running on a treadmill for 10 minutes at 7.5 miles/hour. The dotted lines indicate two periods during which no exercise was performed. (Reproduced by permission from Brouha.[8])

from 1.74 to 3.41 liters/min (96 percent) and 3.48 to 4.65 liters/min (34 percent), respectively. If the bed rest were necessitated by disease processes in a vital organ, the deterioration in physical working capacity would be even greater. Furthermore, even if physical working capacity were known before the onset of disease, it would be difficult to ascertain the diminution due to disease compared to that caused by inactivity.[2]

Transiency of training: Most training studies have not been carried beyond several months duration. A notable exception is that of Katila and Frick,[13] who noted increased performance and lower submaximal heart rate in six subjects after 2 months of programmed training. Three subjects continued to train for 2 years and exhibited further training effects, whereas those who ceased training demonstrated exercise tolerance and heart rate characteristic of their pretrained state. Return to original pretraining values after cessation of training for 14 weeks has been observed.[10] In fact, significant training reversal may be a matter of several days, as is suggested in Figure 4.[8]

The longitudinal study of nine college cross-country runners provided an opportunity to assess the interrelated effects of increased maturity, work load (in terms of intensity and distance run), duration and transiency of training. After 3 months of training and competition, their maximal oxygen uptake increased from 62.1 to 66.6 ml/min per kg.[14] Six runners continued training and, when tested at peak training form 1 to 4 years later, demonstrated a further increase of 6.5 ml/min per kg to 72.0. They had no significant change in body weight during this period. Two of the three who ceased active training and were available for subsequent study had an initial maximal oxygen uptake of 61 ml/min per kg, which increased to 64.6 during training, but then regressed to 58.7 when measured 2 to 3 1/2 years later. These subjects gained approximately 10 percent of body weight during the period of nontraining.

Selected Effects of Endurance-Oriented Training on Normal Middle-Aged Men

Body composition: Physical training has a potentially profound influence on man's body composition, both increasing muscle mass and decreasing fat. However, since K^{40} has been found to be relatively constant in adults over a long period of time, some researchers maintain that change in body composition in the adult population is due to reduction in fat alone, and rarely to increased muscle mass.[15] Moreover, it is unlikely that substantially increased muscle mass is effected by rhythmic, relatively low resistance exercise characteristic of most middle-aged adult physical training programs. Conversely, the energy expenditure of walking, jogging or running over a speed range from 4.6 to 16 km/hour necessitates between 1.4 to 1.7 kcal/kg of body weight per mile traversed,[16] and could result in substantial fat loss.

Longitudinal studies on changes in body composition effected by physical training in middle-aged men have been summarized by Pollock et al.[17] In programs primarily entailing jogging 2 to 4 times a week for periods up to 1 hour for 10 to 24 weeks, the average loss in body weight was 1.4 kg and the mean decrease in percent of body weight as fat was 1.3. Apparently the amount of training is more important than intensity, in that training at 80 to 90 percent of maximal heart rate for 45 minutes 2 days a week for 20 weeks did not cause significant changes in body composition.[18] However, a saturation point apparently occurs, since subjects who trained 30 to 35 minutes for 2 to 3 days a week for 2 years revealed reductions of 3.8 percent of body weight after 6 months and 5.5 percent after 12 months but had no additional change thereafter.[19]

Cardiorespiratory effects: The primary measure of the quality of the cardiorespiratory system is $\dot{V}O_2$ max, which is the product of cardiac output and arteriovenous oxygen difference and reflects both the performance of the heart as a pump and the efficiency of blood flow distribution and oxygen utilization.[20] For young untrained men, the mean value is approximately 50 ml/min per kg, which diminishes with age to about 30 ml/min per kg at age 70.[21] Values as high as 85 ml/min per kg have been noted in highly trained Olympic cross-country skiers and distance runners.[22]

Endurance-oriented physical training of middle-aged subjects for several months increases maximal oxygen uptake. The degree of increase appears to be an interrelation of age, activity level before training, and the intensity and duration of training (Table I; Fig. 2 and 3), but accurate definition of the relative importance of each is presently lacking. Maximal heart rate is either unchanged or slightly lower, whereas oxygen pulse and pulmonary ventilation are increased.[2] The increase in pulmonary ventilation is proportional to that in $\dot{V}O_2$ max, and since arterial blood gas studies indicate that ventilation and diffusion do not limit maximal performance under normal conditions, improvements secondary to training must primarily involve the circulation.[26] In young men this

improvement may occur both by enlargement of cardiovascular dimensions (particularly heart volume, blood volume and total hemoglobin) and by improved function of the circulation itself, although the length of training appears critical to the former.[12]

At submaximal work loads in activities such as walking or riding a bicycle ergometer, there is no appreciable increase in skill with training and, thus, no reduction in oxygen consumption. There is, however, reduced physiologic strain as evidenced by a decreased percent of maximal oxygen uptake at submaximal work loads, and by absolute decreases in heart rate, pulmonary ventilation, blood lactate and ventilatory equivalent.[23,26,31] The reduction in submaximal heart rate is normally associated with an increased stroke volume and perhaps better vasomotor adjustments of blood flow to the working muscles, as is suggested by slightly reduced systemic blood pressures.[23] Because of this improved efficiency, work load capacity at a particular heart rate is augmented.[26] Since cardiac output and oxygen carrying capacity of the blood at submaximal work are the same, or nearly so, improved ventilatory efficiency appears to be due to peripheral factors. The lower level of blood lactate in submaximal work may be due to better distribution of the blood flow or possibly to an increased activation of red muscle fibers with a more efficient energy yield from aerobic processes.[27] The biochemical mechanisms by which this could occur have been established by Holloszy[32] but were derived from animal experiments. More recently, Kiessling et al.[33] have demonstrated that previously sedentary young men who ran 12 miles a week for 28 weeks increased the number of muscle mitochondria. More severe training, as evidenced by the study of elite endurance athletes, showed little difference in the number of mitochondria, but a pronounced size increase as compared to the trained normal young men. Further evidence of the peripheral cardiorespiratory changes effected by training is afforded by Varnauskas and co-workers,[34] who observed a 44 percent increase in succinic dehydrogenase activity (an enzyme probably present only in the mitochondria).

Hemodynamic response: After training, cardiac output is unchanged[35] or slightly reduced during submaximal work.[26,36] Although there is a widened arteriovenous oxygen difference with training in young men,[11] both an increase at greater submaximal work loads[26] and no difference[35] have been noted after training in middle-aged men. Slightly reduced mean systemic arterial blood pressure at submaximal work loads in middle-aged men after training has been observed.[23,35] Since cardiac output is little changed and heart rate and mean blood pressure are reduced at submaximal work, the reduced pressure must indicate that the contractile work of the left ventricle declines slightly.

There is a paucity of data on hemodynamic responses after physical training at maximal exercise levels in normal, middle-aged men. Hence, the hemodynamic response at maximal performance in young men who have undergone endurance training is summarized in Table II. The 15.4 percent increase in maximal oxygen uptake is the result of a nearly equal increase in both arteriovenous oxygen difference and cardiac output. The increased cardiac output was entirely effected by a greater stroke volume, since maximal heart rate was reduced 3 percent. Hartley et al.[35] studied the hemodynamic effects of training on middle-aged men during maximal work, and observed a 14 percent increase in maximal oxygen consumption which was almost entirely the result of increased cardiac output. There was no significant difference in arteriovenous oxygen difference and, since heart rate was slightly reduced, the increased cardiac output and maximal oxygen uptake were entirely a function of a 16 percent increase in stroke volume. There is a close relation between stroke volume and heart volume in young men, which has also been observed in middle-aged, still-active athletes.[38] Both stroke volume and heart volume increase with training in young men,[12] whereas in sedentary, middle-aged men the stroke volume was lower than would be expected from their heart volume, but increased with training concurrent with no change in heart volume,[35] thus suggesting possible improvement in myocardial contractility.

TABLE II
Summary of Findings During Maximal Work in Three Longitudinal Studies on Hemodynamic Effects of Training in Sedentary Young Men (from Saltin[11])

Mazzarella and Jordan[39] examined the possibility of reversing ischemic electrocardiographic exercise responses in seven middle-aged sedentary men who were asymptomatic at rest by subjecting them to 20 minutes of walking three times a week for 8 to 10 weeks. Six men showed less S–T segment depression

TABLE III

Basic Characteristics of Subjects

	Sedentary Normal (no. = 45)	Trained After Infarction (no. = 11)	Postoperative Bypass	
			Untrained (no. = 17)	Trained (no. = 4)
Age (yr)				
Mean ± 1 SD	50.0 ± 5.8	47.6 ± 8.0	50.6 ± 5.6	53.7 ± 8.2
Range	38.9–60.3	38.4–60.9	42.3–62.0	45.0–62.0

in submaximal work after training, five showed improvement at maximal exercise, and only three exhibited S–T segment depression in their immediate postexercise electrocardiogram.

Adaptation to Endurance-Oriented Training in Coronary Artery Disease

With impetus provided by the early work of Hellerstein et al.,[40] physical reconditioning has in the past decade become part of the armamentarium of treatment for patients with coronary artery disease. Several investigators[41–45] have shown that many patients with coronary artery disease can be retrained to perform better than sedentary normal subjects of similar age, although until recently the mechanisms effecting this improvement were not well elucidated.[46] The variability of response to physical training is greater in patients with coronary artery disease, presumably because the severity of the underlying disease limits some patients' ability to respond to the training stimulus.[41,47]

Angina pectoris: Although MacAlpin and Kattus[48] have demonstrated "walking through angina," most investigators have stopped such patients from exercising to the point of maximal effort because of pain; that is, they were symptom-limited.[49] Undoubtedly this procedure underestimates maximal work capacity, since an increase of 14.5 percent in maximal oxygen uptake has been observed in patients with angina after sublingual administration of 0.4 mg of nitroglycerin.[50] Detry and Bruce[51] observed increased maximal oxygen uptake (symptom-limited) after training, and others have noted a greater amount of work before onset of pain, which suggests decreased cardiac oxygen consumption or increased coronary blood supply, or both.[46,52] In addition, Redwood et al.[52] have made observations at the onset of angina that indicate that training might improve myocardial oxygen delivery. In submaximal work, heart rate, mean blood pressure, pressure-rate product, tension-time index and presumably myocardial oxygen requirements are reduced.[5,52–54] In addition, reduced S–T segment depression has been noted.[40,51] Hemodynamic studies have revealed little or no change in cardiac output with a concurrent increase in stroke volume and nearly constant arteriovenous oxygen difference,[53,54] whereas reduced muscle blood flow and a widened arteriovenous oxygen difference at low work loads[55] and increased muscle blood flow at heavier loads of submaximal work[5] have been observed. The latter finding suggests that peripheral factors may also improve myocardial performance, as has recently been substantiated by Detry and Bruce,[51] who found no difference in the tension-time index, S–T segment depression relation at symptom-limited levels of maximal oxygen uptake after training.

Myocardial infarction: Relatively few studies have been made of the effects of physical training on patients after myocardial infarction without significant concurrent angina. Early studies of such patients[40,42–44,47] demonstrated reduced heart rate, S–T segment depression and decreased indirect blood pressure and tension-time index at submaximal work loads. A variety of exercise programs, including walking, jogging, ergometer cycling and endurance calisthenics and games, involving sustained energy expenditures of up to 7 kcal/min (oxygen consumption 1.4 liters/min) for periods of 1 hour, three to five times a week, were utilized in these studies. Increased physical performance has also been demonstrated,[42,43] as has increased maximal oxygen uptake.[41,45]

Comparison of submaximal and maximal cardiorespiratory function of patients after myocardial infarction and coronary bypass grafting with function in sedentary normal subjects: To test safely patients with various degrees of cardiac dysfunction, a slowly progressive multistage treadmill test that permits determination of maximal performance and attendant submaximal and maximal cardiorespiratory responses was developed.[56] The test is initiated at a speed of 50 meters/min, zero grade, and the work load increased every 3 minutes,

first by increasing the speed 10 meters/min to a maximum of 80 meters/min, and then by increasing the inclination 2 percent to a maximum of 22 percent at 42 minutes. Exercise is continued to the point of maximal tolerable effort as defined by dyspnea, leg weakness or electrocardiographic contraindication. Heart rate is recorded periodically, whereas oxygen consumption and associated respiratory metabolism measures are derived by standard procedures from data collected by open circuit metabolism.[56]

A community search revealed 11 men who had trained for 6 months to 11 years after myocardial infarction. Ten were jogging 30 to 45 minutes 3.5 times a week, and one patient swam 45 to 60 minutes, 5 times a week. Subsequently, 17 untrained men were studied 5 to 19 months after single or multiple aorto-coronary bypass grafts. Thirteen had postoperative angiograms to confirm graft patency. One patient continued to have left ventricular failure with patent grafts, two patients had one of two grafts blocked, and one patient with residual angina had occlusion of his single anterior descending artery bypass. Forty-five sedentary normal men of similar ages (Table III) were used for comparative purposes. Student's t test was applied to determine if the mean differences between either of the two patient groups and the sedentary normal group were significant ($P = <0.05$). The comparisons of maximal performance and of submaximal and maximal cardiorespiratory function of the patient groups have inherent limitations and bias: (1) The subjects trained after infarction were not available for study before infarction or training; (2) subjects trained after infarction and those who had undergone coronary artery bypass are not strictly comparable because of differences in severity of disease and training; and (3) subjects trained after coronary artery bypass were not tested preoperatively since assessment of maximal tolerable effort did not seem justified before operation. Within these limitations, however, certain comparisons of the patient groups with the sedentary normal group are informative.

All subjects completed the first seven work loads (stages) encompassing 21 minutes, and only one subject who had undergone coronary artery bypass surgery failed to attempt stage 9 (80 m/min, 10 percent grade), which was accepted as the upper end of submaximal work. Graphic analysis of submaximal data in the three groups is shown in Figures 5 to 7. The close similarity in oxygen consumption values for all groups at submaximal work loads indicates that there was no significant difference in walking skill. Apparent differences between the patients trained after myocardial infarction and normal groups in heart rate, oxygen pulse, pulmonary ventilation and ventilatory equivalent were not statistically significant. On the other hand, differences in pulmonary ventilation and ventilatory equivalent between the normal group and patients who had undergone coronary artery bypass were significantly different over the whole range of submaximal work; values for heart rate and oxygen pulse were significantly different after 15 minutes.

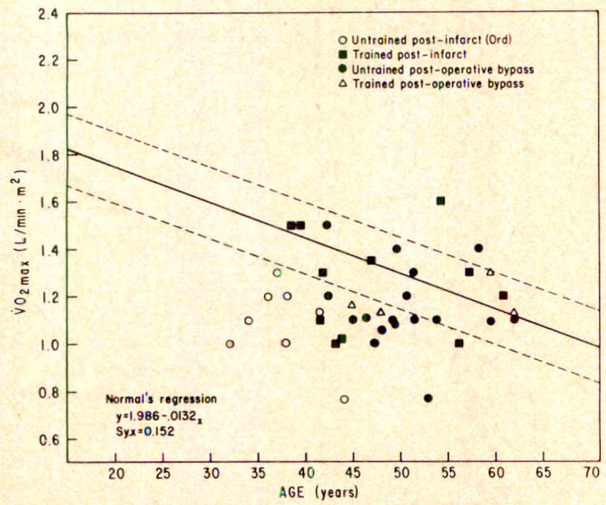

FIGURE 9. Individual values for untrained and trained subjects after myocardial infarction and coronary artery bypass. The **solid line** indicates the regression line for a sedentary normal group; the **dashed lines** represent 1 standard deviation above and below the regression line of the normal subjects.

Mean values for walking time and selected cardiorespiratory responses at maximal tolerable effort for the three groups are summarized in Figure 8. The group values for patients trained after myocardial infarction were similar to those of normal subjects except for significantly lower heart rate and pulmonary ventilation. In four subjects in the former group, maximal efforts should be considered symptom-limited; one patient had angina, one had leg cramps and two had marked ischemic S–T segment depressions and were stopped by the examiner before there was a clear tendency of the oxygen consumption to plateau. On the other hand, all of the coronary artery bypass patients walked to maximal effort, as evidenced by plateauing of oxygen consumption. Nevertheless, compared with the normal subjects, these patients had significantly shorter walking time, lower maximal oxygen uptake, heart rate and oxygen pulse and a higher ventilatory equivalent. Electrocardiographic evidence of myocardial ischemia increased with effort in five patients, four of whom had patent grafts as assessed by angiography. Seven had no change in resting ischemic electrocardiographic changes with effort; the remaining five exercised to maximal level with normal tracings.

Cardiorespiratory adaptation to training after coronary artery bypass: Four of the subjects studied after coronary artery bypass surgery consented to enter a quantitative reconditioning protocol, training at least 3 days a week, 40 minutes a day for 12 weeks by walking and jogging at an intensity necessitating a heart rate of 75 to 85 percent of maximum. Data after training (Table IV) indicate no appreciable change in oxygen consumption in submaximal work, but heart rate in the later work stages increased 4 to 6 beats/min. As a result, the oxygen pulse after training was somewhat lower. Submaximal pulmonary ventilation was essentially the same after training, whereas the response to training of ventilatory equivalent was variable. Clearly, there were no classic training ef-

TABLE IV

Effect of Training 12 Weeks on Cardiorespiratory Function in Four Coronary Artery Bypass Surgery Patients

Variable	Stage 1(0–3:00)		Stage 4(9–12:00)		Stage 7(18–21:00)		Stage 9(24–27:00)		Maximal Tolerable Effort	
	T_1	T_2	T_1	T_2	T_1	T_2	T_1	T_2	T_1	T_2
Oxygen uptake (ml/min per kg)	8.0	8.9	13.7	13.8	19.2	19.5	24.1	25.2	28.6	31.7
Heart rate (beats/min)	88	87	97	101	122	126	144	150	160	170

T_1 and T_2 indicate, respectively, test results before and after training.

fects at submaximal work of the type seen in normal subjects[27] and patients after myocardial infarction.[44,45,54] Data at maximal work loads reveal higher heart rate and maximal oxygen uptake but little change in oxygen pulse, pulmonary ventilation and ventilatory equivalent.

Significance of cardiorespiratory training responses in coronary artery disease: The group trained after myocardial infarction evidenced no atypical physiologic strain in providing submaximal energy requirements. Conversely, however, patients studied after coronary artery bypass did, as denoted by increased pulmonary ventilation, ventilatory equivalent and heart rate, and lower oxygen pulse during submaximal work. Furthermore, no significant changes in submaximal work responses occurred in the four subjects who underwent coronary artery bypass surgery and trained for 12 weeks. A substantially higher heart rate at submaximal work loads than that of sedentary normal subjects is characteristic of untrained patients after myocardial infarction,[49,57,58] whereas a reduced heart rate and decreased pulmonary ventilation at submaximal work loads have been observed in patients trained after myocardial infarction.[40,45,53–55] Hence, even though the submaximal heart rate of the subjects trained after infarction was not significantly lower than that of the normal group, it should not be assumed that there was no training effect in these patients. Further evidence supporting this contention is afforded in Figure 9. The bold line represents the regression line of maximal oxygen uptake (liters/min per m^2) with age; the dashed lines represent ±1 standard deviation for 80 sedentary normal men aged 31 to 69 years[56]; the open circles indicate maximal oxygen uptake values from treadmill studies of untrained patients studied after myocardial infarction by Ord.[59] As can be seen, none of the values for these subjects fall within 1 standard deviation of the normal subjects' age-related regression line. On the other hand, the maximal oxygen uptake values of six of our subjects trained after myocardial infarction are above the line, and that of a seventh patient falls within 1 standard deviation. However, four values fall significantly below the line (more than 1 standard deviation), thus emphasizing the individual variability of maximal exercise response in patients after myocardial infarction, as noted by others.[41,47] The comparisons of group mean values for myocardial oxygen consumption in Table V lend further credence to the assumption that a significant training effect had occurred in our subjects trained after myocardial infarction.

Of the 17 patients who were not trained after coronary artery bypass surgery, the values of 9 were significantly below normal (more than 1 standard deviation) (Fig. 9). Their heart rate and pulmonary ventilation were normal, but maximal oxygen pulse was significantly decreased, which is indicative of reduced stroke volume or arteriovenous oxygen difference, or both. Their ventilatory equivalent, which reflects the amount of ventilated air necessary for utilization of 100 ml of oxygen, was significantly greater. In view of the normal ventilatory capacity evidenced, increased ventilatory equivalent could be a reflection of decreased diffusing capacity in the lungs, but more likely is a secondary indication of reduced stroke volume or decreased capacity for oxygen utilization at the muscle cell level, or both. The maximal oxygen uptake of the subjects studied after coronary artery bypass was intermediate to that recorded in previous studies for untrained and trained patients after myocardial infarction (Table V). The four subjects who trained for 12 weeks sustained a 10.8 percent increase in maximal oxygen uptake to a value comparable with that of other subjects trained after myocardial infarction. In addition, their walking time increased, as did their maximal heart rate (by 10 beats/min). Since oxygen pulse, pulmonary ventilation and ventilatory equivalent changed little, the primary mechanism for enhanced oxygen delivery at maximal effort appears to be an increased heart rate, which is uncharacteristic of trained normal subjects but has been noted previously in other subjects after myocardial infarction.[41,45]

TABLE V

Comparison of Maximal Oxygen Consumption in Untrained and Trained Postmyocardial Infarction Patients

Study	no. of Subjects	Untrained	Trained	Training Duration	Training Time/ Week (min)
Ord[59]	8	27.4*	—	—	—
Kasch & Boyer[41]	11	19.9	30.6	6 mo	210
Kasser & Bruce[49]	28	26.5†	—	—	—
Detry et al.[45]	6	27.3	32.2	3 mo	135
Present study					
Trained after infarction	11	—	32.0	6 mo to 11 yr	160
Untrained after CAB	17	28.6	—	—	—
Trained after CAB	4	28.6	31.7	12 wk	120

CAB = coronary artery bypass sugery.

* Assuming body surface area of 1.90 m^2 and body weight of 75 kg.

† Calculated from formula for estimating maximal oxygen consumption from treadmill walking time and assuming body weight of 75 kg.

The primary distinction between the exercise response of our two patient groups is that the subjects trained after myocardial infarction evidenced no differences from normal subjects at submaximal work loads and had only slight evidence of reduced maximal energy production, whereas the untrained subjects who had undergone coronary artery bypass surgery demonstrated impaired performance at both submaximal and maximal work loads, as has also been noted in other untrained patients after myocardial infarction.[49] Although the four subjects trained after coronary artery bypass had increased maximal energy production, they had no significant change in their atypical submaximal cardiorespiratory responses. The physiologic mechanisms for these findings are not really discernible without hemodynamic measurements.

Conclusions

Our data indicate the following: (1) Most subjects trained after myocardial infarction can achieve the performance levels of normal, sedentary subjects, but some do not exhibit a classic training effect, probably because of residual myocardial dysfunction. (2) Successful coronary artery bypass surgery does not entirely normalize work performance, metabolic or hemodynamic function, although angina and electrocardiographic changes can be reduced. (3) Work performance and aerobic power of patients after coronary artery bypass can be further improved by physical training, although the physiologic mechanism for these changes is not readily apparent.

Physical training improves cardiorespiratory function, which may be indicative of improved myocardial function, and aids in reducing coronary artery disease risk factors.[4,26] However, because of the relatively small number of patients studied longitudinally and the complex etiology of coronary artery disease, no conclusive evidence of less frequent recurrence rates or greater longevity has been demonstrated, although the recent report of Rechnitzer et al.[60] indicates some encouraging initial findings.

Physical Activity After Myocardial Infarction

WILLIAM L. HASKELL, PhD

Stanford, California

Experimental and clinical research has provided substantial knowledge of the potential benefits and risks associated with the performance of physical activity by patients with uncomplicated myocardial infarction. This knowledge has resulted in the earlier mobilization, a reduction in length of hospitalization, an increase in physical working capacity and a more successful return to work of many patients. These improvements have been associated with a variety of physiologic and psychological changes produced by increased activity during each stage of the patient's recovery. During hospitalization, changes in posture and low intensity activity minimize the cardiovascular and psychological complications caused by prolonged bed rest. After hospitalization, the most valuable benefit of regularly performed exercise appears to be a reduction in myocardial oxygen demand at rest and during submaximal exertion. The unique contribution of increased physical activity to reducing the frequency and severity of reinfarction has not been adequately established but, when combined with other behavior designed to reduce risk factors, the preliminary results are favorable. For these benefits to be obtained without undue risk, exercise for the postmyocardial infarction patient needs to be individually prescribed and periodically reevaluated.

Definitive evidence is not yet available to document the unique influence of physical activity performed after myocardial infarction on subsequent cardiovascular morbidity or mortality. Numerous studies have yielded favorable preliminary or short-term results in that selected patients after acute myocardial infarction have benefited from "appropriate increases in physical activity"; they have (1) had fewer complications associated with bed rest,[1] (2) made a more successful psychological adjustment to their disease,[2] (3) shown improved cardiovascular function and physical working capacity,[3] (4) returned to gainful employment earlier and more frequently,[4] and (5) had fewer and less severe reinfarctions.[5]

Although additional research is required to determine more accurately the benefits derived by such patients from increased activity and to define how these benefits can be achieved most economically, sufficient data and experience are available to provide useful guidelines for the organization and implementation of the physical activity aspect of a cardiac rehabilitation program.[6] Recommendations for integrating increased physical activity into a total program of cardiac rehabilitation have been described previously and should include when necessary medical therapy, health education, diet modification, reduction of stress or tension, abatement of cigarette smoking, and psychological, social and vocational counseling.

The physical activity component of a comprehensive rehabilitation program should be implemented to meet the patient's specific needs during each stage of recovery. For the patient with uncomplicated

myocardial infarction who has been admitted to the coronary care unit, a physical activity program can be organized into five rather arbitrary stages: (1) coronary care unit, (2) remainder of hospital stay, (3) a 2 to 8 week period of convalescence, (4) physical reconditioning, and (5) activity maintenance.

The activity at each stage should be systematically prescribed by a knowledgeable physician after a careful evaluation, and it should be supervised or monitored by a physician or well trained allied health personnel. The exact nature of the evaluation, supervision and monitoring will depend upon the patient's clinical and functional status. As recovery progresses, the specific activities performed and the immediate objectives of the exercise plan will change, but the general principles of exercise evaluation, prescription and training will remain the same.[7]

Coronary Care Unit Activity Program

The primary purposes of early performance of physical activity in the coronary care unit are to counter the potentially harmful deconditioning effects of prolonged bed rest and to minimize the psychological trauma of coping with the realities of surviving a myocardial infarction. In many cases the patient is unable to distinguish between a nonspecific consequence of extended inactivity and the debility directly produced by cardiac limitation resulting from the infarction. Conditions caused or aggravated by bed rest and alleviated to some extent by changes in posture and activity include decreased cardiovascular function manifested by orthostatic hypotension, venous thrombosis, reduced lung volume, atelectasis and reduced skeletal muscle tone and joint flexibility.[8]

Potential hazards of exercise: The major hazards of inappropriate exertion soon after acute myocardial infarction are considered to be the precipitation or aggravation of serious arrhythmias, congestive heart failure, aneurysm formation and cardiac rupture. However, only the hazard of an increase in premature ventricular beats during exercise by patients with coronary heart disease has been firmly documented.[9–11] There is conflicting evidence on the potential dangers of cardiac rupture or aneurysm formation with exertion immediately after infarction. The report of Jetter and White[12] that cardiac rupture occurred in 73 percent of severely psychotic patients who probably remained active during an acute myocardial infarction and died is not confirmed by recent studies of cardiac rupture occurring during sudden death in noninstitutionalized adults.[13,14] However, since in man most of the necrotic tissue resulting from the infarction is not replaced by connective tissue for about 2 weeks and complete healing requires 4 to 8 weeks,[15,16] the myocardium probably should not be subjected to major increases in heart rate or blood pressure for at least several weeks.

Animal studies: In animals, the effect of vigorous exercise soon after artificially induced myocardial infarction appears to be quite benign. Thomas and Harrison[17] found that after experimentally induced acute myocardial damage in rats severe restriction of activity increased mortality, whereas enforced vigorous exercise had no detrimental effect. Kaplinsky et al.[18] and Thompson et al.[19] were not able to reproduce the earlier findings of Sutton and Davis[20] of an increase in aneurysm formation when dogs were exercised beginning 3 days after coronary arterial ligation.

Kaplinsky et al.[18] exercised dogs vigorously for 1 hour daily for 5 weeks starting 3 days after acute myocardial infarction produced by coronary arterial ligation; these animals had no increase in size of infarction, frequency or size of aneurysms, or instances of cardiac rupture or sudden death when compared to a nonexercised control group. Similar results were obtained by Thompson et al.[19] when dogs were exercised vigorously (peak heart rates exceeding 220 beats/min) within 1 hour of total occlusion of the left anterior descending coronary artery. The results of such animal studies need to be considered with caution since they are not likely to be applicable to patients in a coronary care unit. Healthy dogs with a single artificially induced coronary occlusion without previous myocardial damage probably do not provide an acceptable model for the extrapolation of results to the diseased human heart with diffuse coronary atherosclerosis and previous myocardial necrosis.

Clinical studies: The clinical rationale for early sitting and physical activity of patients after myocardial infarction was presented in 1940 by Levine[21] and in 1944 by Dock[22] and Harrison.[23] They cautioned against unnecessary bed rest and promoted the idea of frequent postural changes for the patient and early participation in self-care activities. Their primary concerns were the complications of phlebothrombosis, embolization and congestive heart failure associated with extended bed rest and the development of "cardiac neurotics" as a result of unnecessary and prolonged restriction. In the 1950's the concept of the "armchair" treatment was promoted by Levine.[24]

Levine and Lown[25] demonstrated that cardiac output was reduced by 23 percent when patients who had had a myocardial infarction changed from a supine position to sitting in a chair. Coe[26] found the mean cardiac work in such patients to be 23 percent less while sitting than while reclining. More recently, DeBusk et al.[27] demonstrated that changes in posture or selected passive and active exercises can be performed by patients in the coronary care unit without significant increases in work of the heart (blood pressure-pulse rate product) or ventricular arrhythmias. Fareeduddin and Abelmann[28] have demonstrated that the impaired orthostatic tolerance produced by complete bed rest in many patients after infarction is preventable or reversible by early ambulation or modified bed rest allowing passive movements and occasional sitting.

Activity program in the coronary care unit: For the patient with the uncomplicated myocardial infarction (no evidence of shock, heart failure, intractable angina, or uncontrolled arrhythmia) low level passive and active isotonic activities normally can be

initiated in the coronary care unit. These activities should be carried out under the direction of the patient's physician or the medical director of the coronary care unit, or both. Acceptable activities and techniques for their instruction and supervision have been described in detail.[6,27,29] Usually included at this time are self-care activities (self-feeding, washing of face and hands, shaving, use of bedside commode with assistance), active and passive movements of arms and legs while in bed and changes in posture to include sitting on the side of bed with feet supported or in a chair. All of these activities should be supervised by a well trained nurse or therapist with continuous electrocardiographic monitoring and periodic evaluations of blood pressure and symptoms.

Indications of an inappropriate increase in exertion during the coronary care unit activity phase include (1) unexpected fatigue, weakness or dyspnea, (2) development of or increase in angina, (3) significant rhythm or conduction disturbances, (4) increased ischemic-type S-T segment displacement, and (5) increase in heart rate by more than 20 beats/min over the resting rate or a decrease by more than 10 beats, and (6) a persistent decrease or substantial increase in systolic blood pressure. If any of these responses occur during activity, bed rest should be resumed until the patient's status is evaluated and a revised activity plan developed.

Activity During Remainder of Hospital Stay

Upon transfer from the coronary care unit and in the absence of cardiovascular complications the patient should continue a planned program of individually prescribed activity. The major objectives of physical activity during this stage are to continue to prevent the harmful physiologic and psychological effects of prolonged bed rest, reduce the duration of hospitalization and increase cardiovascular functional capacity to a level that will allow a reasonable degree of self-care after discharge and a more rapid return to work.

Mobilization of patients after discharge from the coronary care unit and the effects of a shortened hospital stay have been evaluated by several groups.[30–32] In general these studies have demonstrated that there are no adverse clinical effects from early mobilization in selected patients after myocardial infarction and that there may be some benefit by the reduction of physiologic and psychological complications and an earlier or more frequent return to work. The rationale for and success rate of early mobilization and discharge after myocardial infarction were recently reviewed by Rose.[33]

Activity program: Appropriate activities during this phase of recovery include longer periods of sitting in a chair, increased self-care activities, rhythmic exercises using arms, legs and trunk, and slow ambulation in the hospital room and later in the corridors. For patients who progress rapidly, limited stair climbing might be permitted during the latter portion of this phase.[34]

Increases in exertion should be performed by the patient at least several times a day unless contraindicated by signs or symptoms. Each activity session should have alternating periods of exercise and rest. These sessions should not be conducted immediately after meals and can be supplemented by calisthenics performed while in bed. Unnecessary isometric exercises, particularly in conjunction with a Valsalva maneuver, should be avoided. During and after each new activity the patient should be evaluated for changes in electrocardiogram, blood pressure and heart sounds.

During the latter stages of hospitalization, instructions should be provided to the patient and his family about particular activities to be performed or avoided after leaving the hospital. Topics that need to be covered include sexual activity, use of stairs, lifting and carrying of relatively heavy objects and activities in hot, cold or humid environments.

Testing of functional capacity: One means of improving the appropriateness of the recommendations on physical activity to the patient going home is to carefully evaluate his symptom-free functional capacity while he is still in the hospital. This can be achieved by monitoring the electrocardiogram, heart sounds, blood pressure and symptoms during ambulation in the corridor or during stair climbing. Low level multistage exercise testing using either a stationary bicycle ergometer or treadmill as soon as 3 weeks after infarction has been demonstrated to be safe and can provide useful prognostic information as well as objective criteria for exercise prescription.[35]

Activity Program During Convalescence

The primary goals of an activity regimen during this phase of recovery are (1) to increase gradually the frequency, duration and intensity of activity so that by the 8th to the 12th week after infarction the patient with an uncomplicated infarction has achieved a level of exertion commensurate with that required by the job to which he is scheduled to return, and (2) to provide psychological support to the patient and family for the prospect of successful long-term recovery. If return to work is not a consideration or if the job requires a peak energy expenditure greater than 6 to 8 METS (multiples of resting oxygen consumption) then the activity level during this time should reach that necessary for complete self-care and the safe performance of selected leisure time activities, including limited sexual activity.

An objective evaluation of the effects of increased activity between the 4th and 12th weeks after infarction has been reported by Brock.[36] As a result of an 8 week exercise program (1 hour, three times a week) his patients had a small reduction in pulse rate at the same work load and a large (60 to 70 percent) increase in physical working capacity and peak oxygen consumption. The increases in working capacity and oxygen consumption are difficult to interpret because of a change in the criteria for terminating the exercise test from a pulse rate of 65 percent of the age-

TABLE I

Indexes of Myocardial Oxygen Demand Before and After Physical Conditioning in Male Patients with Cornary Heart Disease

Study	Patients (no.)	Age (yr)	Index	Rest		Exercise		Exercise Intensity
				Before	After	Before	After	
Redwood et al.[43]	7	48	Triple product	...	...	4300	3521	Same submaximal workload
						4300	4885	At onset of angina
Frick & Katila[41]	7	47	Tension-time index	2519	2941	5168	4382	Same submaximal workload
			Double product	103	107	262	242	Same submaximal workload
Clausen et al.[42]	9	52	Tension-time index	2470	2380	3943	3393	Same submaximal workload
			Double product	...	...	204	166	Same submaximal workload
Hellerstein[40]	100	49	Double product	...	...	248	193	Same submaximal workload
Detry et al.[39]	12	49	Double product	81	64	116	94	45% of pretraining $\dot{V}O_2$ max
						166	137	75% of pretraining $\dot{V}O_2$ max
Kasch & Boyer[44]	11	50	Double product	106	85	163	156	286 kg-m before; 382 kg-m after
						247	296	Maximal workload

Double product = [heart rate (beats/min) × systolic arterial pressure (mm Hg)]/100; kg-m = kilogram-meters of work per minute; tension-time index = area under systolic brachial arterial pressure curve × heart rate (mm Hg sec/min); triple product = heart rate (beats/min) × systolic arterial pressure (mm Hg) × ejection time (seconds); $\dot{V}O_2$ max = maximal oxygen consumption.

adjusted maximum before training to a pulse rate of 75 to 80 percent after training. How much of the improvement in physical working capacity during convalescence is due to the natural recovery from the infarction and bed rest and how much is due to the conditioning program has not been established.

Activity program: Most usual light household and self-care activities can be permitted except floor scrubbing, hand washing and hanging of clothes, bed making and similar activities requiring prolonged or vigorous effort with the arms and shoulders. Again, isometric exercises using the arms, such as those required in carrying heavy objects like a suitcase, need to be avoided. Jackson et al.[37] have demonstrated that this type of activity can create a disproportionate work load on the myocardium in relation to total body energy expenditure.

The patient who remains asymptomatic should gradually increase his level of activity at his own pace so that by the end of the 4th or 5th week after infarction he can walk a total of 1/2 to 1 mile a day comfortably. These walks should be divided into two or three periods of approximately equal duration. The program should remain within each patient's capabilities and he should remain symptom-free.

Before increasing the pace and distance of exercise further in the 6th through 8th weeks after infarction, the patient should be carefully reevaluated by his physician. This assessment should include a medical history, with careful questioning about the level of daily activity the patient has reached and his symptomatic response to this activity, physical examination, and appropriate laboratory tests including a resting electrocardiogram.

Functional assessment: Cardiac function should be assessed by a multistage exercise test in which the highest work load performed is greater than that of the activities performed by the patient during the previous week, such as walking half a mile or stair climbing. The response to this effort test can serve as a valuable guide to the physician in regulating the patient's future activities. Adverse responses to the exercise test, which indicate a need to decrease rather than increase activities, include a disproportionately rapid and large rise in heart rate or blood pressure, a sustained reduction in systolic blood pressure of more than 10 mm Hg, significant changes in the electrocardiogram, increasing angina, or a decrease in working capacity.

The patient with an improved exercise test response should be advised to increase the duration and speed of walking during the next several weeks in order to increase his endurance and strength in preparation for his return to work. In general, in the patient who has shown no adverse response to the preceding carefully monitored graduated activity program, a reasonable goal is to obtain a capacity for walking a mile in 20 to 25 minutes at least once a day, with a peak level of energy expenditure not exceeding 4 to 5 METS. The principles of exercise prescription for coronary heart disease patients have been presented in detail by Hellerstein and co-workers.[38]

Physical Conditioning

Many patients without clinical complications 8 to 24 weeks after infarction become candidates for a program of higher intensity physical activity. The major objectives of such a physical conditioning program are to (1) improve physical working capacity, (2) decrease symptoms and signs of ischemic heart disease at rest and during exertion, (3) increase speed and frequency of return to gainful employment, and (4) reduce the chances of reinfarction or sudden death. Whether or not these changes take place appears to be dependent upon a combination of hemodynamic, metabolic and psychological alterations.

Hemodynamic and Metabolic Changes

In many respects the hemodynamic and metabolic changes that occur in cardiac patients with conditioning are quite similar to the changes seen in their age-matched asymptomatic, sedentary counterparts except that the magnitude of change is usually less and the interindividual variability is substantially greater for the former.[3] Some factors contributing to this variation in conditioning response include age, degree of myocardial necrosis and ischemia, interval after infarction, cardiovascular functional capacity at the start of training and the magnitude of the conditioning stimulus (intensity, duration and frequency). Also, the load (resting, submaximal or maximal) and body position (lying, sitting or standing) at which hemodynamic measurements are determined influence the nature and magnitude of measurable changes.

Improvement produced by physical conditioning in the working capacity and clinical manifestation of many patients after infarction results from a reduction in the discrepancy between myocardial oxygen supply and demand due primarily to a decrease in demand. A reduced myocardial oxygen demand at rest and submaximal exercise is reflected by a significant reduction in such indexes of myocardial oxygen requirement as pressure-rate product,[39,40] tension-time index[41,42] and the triple product[43] (heart rate [beats/min] × systolic arterial pressure [mm Hg] × ejection time [seconds]) (Table I). Major changes contributing to the lowering of these indexes are bradycardia and a decrease in systemic arterial pressure.[44] The bradycardia is usually associated with a small increase in both stroke volume and arteriovenous oxygen (a–v O_2) difference[45] resulting from increases in skeletal muscle mitochondria size and number with augmented levels of activity by the mitochondrial respiratory enzymes.[46]

Increases in physical working capacity and aerobic capacity in patients not limited by manifestation of ischemic heart disease before conditioning have been reported.[39,43,44,47] Whether these changes result from an expanded a–v O_2 difference, a greater stroke volume or a combination of both as seen in healthy young adults has not been measured.[3] Extrapolations from hemodynamic measurements made during submaximal exercise indicate that increases in either a–v O_2 difference[39] or stroke volume[42] may be the major contributor to this enhanced capacity. Patients with substantial myocardial damage or ischemia resulting in poor left ventricular compliance probably are extremely limited in their ability to increase stroke volume with physical conditioning.

Changes in coronary circulation: Studies using coronary arteriography do not support the hypothesis that physical conditioning contributes significantly to coronary artery collateralization in patients with coronary artery disease as observed in some animal studies.[48,49] Ferguson et al.[50] studied 14 patients with significant obstructions in one (6 patients) or two (8 patients) coronary arteries who exercised three times a week for 13 months. The average increase in maximal oxygen consumption was 25 percent (21.9 ± 4.8 to 27.4 ± 4.1 ml/kg per min) but only two patients with progressing obstructions manifested new collateral vessels. Similar results were observed by Conner and La Camera[51] in patients who underwent 6 months of physical conditioning after myocardial infarction.

Redwood et al.[43] found that as a result of physical conditioning the level of the triple product at which angina occurred was increased in some patients, possibly as a result of increased myocardial oxygen supply. Similar results using S–T segment displacement as a measure of ischemia have been reported by Kasch and Boyer,[44] but Detry and Bruce[47] found no significant decrease in S–T segment depression at the same double product. Such changes could result from a reduced myocardial oxygen requirement due to a more synchronous contraction and smaller heart volume during exertion or a slight increase in myocardial oxygen extraction without any increase in coronary blood flow.

Other alterations possibly resulting from physical conditioning activities but not well defined in patients who have had a myocardial infarction include decreases in serum lipoproteins, especially triglycerides,[52] a reduction in plasma insulin,[53] enhancement of blood coagulation and fibrinolytic activity[54] and decreases in plasma catecholamine levels.[55] If some of these changes do occur they could reduce the patient's risk of reinfarction or sudden death.

Some of the improvements seen in the physical working capacity and physiologic responses to exercise by patients after myocardial infarction may be the result of psychological changes associated with their participation in a physical conditioning program. Both objective and subjective measures indicate that, for many such patients, physical conditioning results in a reduction in depression and hypochondriasis, an increase in self-confidence, particularly as it relates to the performance of physical tasks, and an improved sense of well-being.[40,56] In general, the magnitude of psychological improvement appears to be related to the degree of neurosis or anxiety upon entrance into the program and may be due more to the attention received during supervised exercise programs than to the effects of the activity itself.[2]

Recurring Myocardial Infarction and Mortality

The influence of physical conditioning on the frequency and severity of recurring myocardial infarction has not been adequately defined using random allocation of a sufficiently large number of patients into exercise and control groups. Table II contains a comparison of the mortality rates reported for patients who participated in a program of active rehabilitation after infarction and patients with similar characteristics who did not participate in any structured program. A consistently more favorable mortality rate is shown for the rehabilitation program participants; however, there are serious questions as to the comparability of the active and nonactive groups in each study regarding the severity of illness and the likelihood of reinfarction. Also, other coronary heart disease risk factors were not well controlled and sometimes intentionally altered as a part of the rehabilitation program.

The only reported study using a randomized control design in which reinfarction and mortality rates were analyzed showed no differences between supervised exercise program participants and control subjects.[61] Of 298 consecutive male patients under age 65 who were treated in the University Central Hospital, Helsinki in 1969 with a diagnosis of acute myocardial infarction, 158 met the criteria 6 to 8 weeks after hospital admission for a study of supervised physical activity. On the basis of their year of birth, the patients were randomly assigned during their hospital stay into control (odd year) and training (even year) groups. Control group participants received regular medical care; the training group members were requested to participate in a supervised exercise program approximately 1 hour three times a week during the first five months and then twice a week from the 5th to 12th months. During the first 20 months after initiation of the training program, of the 81 control patients 4 had a nonfatal reinfarction and 7 died from reinfarction; of the 77 training group patients, 6 had a nonfatal reinfarction and 8 died from reinfarctions. These differences were not statistically significant. A major limitation of this study was the poor adherence by the training group patients to the supervised exercise program.

Return to gainful employment: Whether physical conditioning increases the speed and frequency at which patients who have had a myocardial infarction return to gainful employment has not been satisfactorily determined. Kentala[61] found no difference in his exercise and randomly allocated control groups, whereas Kellerman et al.[62] observed an increase in frequency of return to work among rehabilitation program participants. For economic reasons, a definitive answer to this question needs to be determined but will be extremely difficult to obtain because the number of patients returning to work after a myocardial infarction depends, to a large extent, on factors other than their clinical status or physical working capacity.[63]

TABLE II

Deaths Due to Myocardial Infarction in Rehabilitation Program: Participants and Nonparticipants

Study	Death Rate Due to Recurrent Myocardial Infarction (no. per 100 man years experience)	
	Rehabilitation Program Participants	Comparison Group
Hellerstein[40]	1.95	4.5–6.0*
Gottheiner[57]	3.6	12.0
Brunner[58]	3.1	10.8

	Observed	Expected†
	3.1%	11.2%

* Usual mortality rate of comparable coronary subjects treated in traditional manner as stated by author.

† Based on follow-up experience of 180 patients with myocardial infarction admitted to four local hospitals and discharged alive.

Supervised Conditioning Programs

Because patients who have had a myocardial infarction are at increased risk of exertion-induced cardiac arrest, it is generally recommended that their participation in physical conditioning programs be supervised by a knowledgeable exercise leader and physician or nurse trained and authorized to perform cardiopulmonary resuscitation.[60] How long patients should be under medical supervision while performing relatively high level exercise has not been established. Many cardiac rehabilitation programs in the United States graduate patients to nonsupervised conditioning exercise programs 1 year after infarction; others suggest supervision on an indefinite basis for safety reasons.[60]

A second reason for encouraging supervised programs is the reasonably frequent experience that patients who attend supervised exercise sessions after infarction tend to stop exercising if they are provided an exercise program to perform on their own.[59,64] To determine which patients should have supervision for how long, it is necessary to be able to select accurately those patients who are at very low risk of cardiac arrest or myocardial infarction produced or aggravated by exertion. Those patients at low risk can be encouraged to exercise on their own using an individualized exercise prescription based on and revised periodically according to the results of a medical reevaluation. Because of advanced age, cardiovascular complications or other health problems, certain patients cannot increase their level of exertion above that

achieved during the convalescent stage and should be discouraged from doing so.[65] The inability of patients with a low physical working capacity to increase their capacity after 6 months of regular participation in a conditioning program is considered an indication for reevaluation and possibly alternative therapy.[34]

Conditioning program activities usually include walking, jogging, running, stationary bicycling, swimming, calisthenics and selected games. The intensity, duration and frequency of activity should be prescribed on an individualized basis. Intensity for these types of activities can be at 60 to 85 percent of the patient's physical working capacity as measured by a multilevel exercise test.[38] Recommended duration is 30 to 60 minutes at a frequency of three to five times a week.

During the early phases of physical conditioning, exercise bradycardia occurs only when trained skeletal muscles are used. For example, Clausen et al.[66] trained two groups of men using a bicycle ergometer; one group used their arms while the other used their legs. When tested with arm and leg cycling after training, the men had a lower heart rate only when using the trained limbs. Thus, if one of the objectives of the conditioning program is to improve physical working capacity for a task that requires arm work, then activities using the arms should be included. If arm exercises are used it is important to remember that the double product is higher for arm work than for leg work having the same total body oxygen requirement. Also, because of the low arm strength of many adults it is important to keep the resistance level in arm exercises low in order to avoid the rapid increase in myocardial oxygen demand resulting from a pressure response produced by isometric or heavy resistance activity.[37]

Maintenance Activity Program

Once a desirable cardiovascular functional capacity has been achieved, a long-term program of exercise maintenance should be considered. The goal of this program should be to provide the patient with a level of activity that will maintain his cardiovascular functional capacity and efficiency, assist in maintaining optimal body weight and help him to retain a physical working capacity commensurate with his occupational needs and leisure time interests.

A critical factor in the design of a maintenance program is the decision as to whether it should be performed only with medical supervision. Sufficient follow-up data are not available to determine the susceptibility of a particular patient to cardiac arrest or reinfarction precipitated by an increase in physical activity. In an attempt to make such a decision, all pertinent clinical and laboratory data on the patient should be considered with emphasis placed upon a recent near-maximal or maximal multilevel exercise test. Performance at a level of 10 to 12 METS without symptoms or adverse effects would indicate that at least for the present time activity such as jogging, moderate running, hiking, swimming, doubles tennis, badminton and most gardening are within the patient's capacity. Additional information about the acceptability of a particular activity can be provided by ambulatory electrocardiographic monitoring. This might be particularly useful if the activity includes intermittent exercise loads, heavy use of the arms, and psychological stress such as that possibly associated with competitive sports or anxiety-producing work situations, or major changes in environmental conditions (temperature, humidity or altitude).

The maintenance plan should include a variety of activities that can be performed well within the patient's functional capacity, are of interest to him, and are primarily aerobic but still of sufficient duration and intensity to maintain an "appropriate functional capacity."

Conclusions

By proper patient selection, exercise prescription, program supervision and periodic reevaluation, patients recovering from an acute myocardial infarction can safely perform increasing levels of physical activity. Substantiated benefits derived from increased activity include fewer complications due to bed rest and an increased symptom-free working capacity as a result of improvement in hemodynamic and metabolic function. As a part of a comprehensive cardiac rehabilitation program, physical activity aids in reducing psychological maladjustment and improves success of return to gainful employment. Definitive evidence as to the benefit of increased activity on future cardiovascular morbidity or mortality of patients with coronary heart disease requires a multicenter, cooperative secondary prevention trial. Concurrently with such a major research project, present knowledge of the benefits derived from effectively operated cardiac rehabilitation programs justifies the expansion of these services and increased third-party payment for medically operated programs.

Coronary Heart Disease as a Pediatric Problem

Prevention Through Behavior Modification

JOHN L. BOYER, MD

San Diego, California

Risk factors for coronary heart disease may be present in early childhood. Primary prevention of coronary atherosclerosis requires early identification and vigorous management of risk factors, and the pediatrician and family physician have a major role in this approach. Alteration of behavior with emphasis on exercise of the endurance type and more rational dietary habits are advocated. The beneficial effects of exercise may occur without alteration of coronary risk factors. Early institution of educational programs and constructive physical activity has the potential to influence favorably cardiovascular health at an early stage.

Predictive and preventive cardiovascular medicine should begin early in life. Current emphasis on this approach is based on recent appreciation of the early appearance of coronary risk factors in the pediatric age group and the potential for their alteration by systematic evaluation and management.[1] Most of these risk factors, such as hyperlipidemia, hypertension, cigarette smoking, obesity and physical inactivity, have been attributed to a combination of genetic and environmental influences[2] and, to the extent that the latter effect is operative, these factors are amenable to modification. Recent epidemiologic studies have demonstrated a considerable prevalence of indicators of high coronary risk in children in the teen and preteen years. These have included elevated serum levels of cholesterol and triglycerides,[3–5] obesity,[5–8] hypertension[5,8] and inadequate exercise capacity.[5]

The magnitude and early onset of the problem are exemplified by recent data. Thus, in one study of 95 boys aged 8 to 12 years, 63 percent of the group had one or more coronary risk factors and 17 percent had two or more risk factors.[5] Serum cholesterol was greater than 200 mg/100 ml and triglycerides were greater than 100 mg/100 ml in 20 percent and 8 percent, respectively, of the subjects; 13 percent of the group demonstrated obesity (greater than 25 percent body fat). In another study of more than 4,800 school children 6 to 18 years old, serum cholesterol was greater than 220 mg/100 ml in 5 percent, blood pressure exceeded 140/90 mm Hg in 2 percent of those older than 9 years and 12 percent were obese.[8]

Although applicability of adult coronary risk factors as predictive indexes in children has not been substantiated by long-term studies, the extent of the current coronary epidemic and its potential for mitigation by early intervention have resulted in major interest in the pediatric aspects of management. This approach to early reduction and prevention of known coronary risk coronary factors in childhood constitutes primary prevention.

Primary Prevention

Primary prevention of those influences associated with atherosclerosis should be a principal goal of the pediatrician and family physician. Applying this concept may entail a fundamental reorganization

of pediatric care, permitting certain aspects of treatment of routine upper respiratory and gastrointestinal problems and performance of standard immunizations and regular physical examinations to be handled by paramedical personnel, such as the pediatric nurse-practitioner, so that the pediatrician's time can be spent more beneficially in preventive medicine. The expertise of the physician should be directed to detection of the risk factors that predispose to premature atherosclerosis. In addition, his time and effort should be spent in counseling the family, particularly the mother, in early modification of life style patterns.

Through such efforts by the pediatrician and family physician, the initial formation of constructive patterns for early modification of factors associated with high coronary risk during childhood may be accomplished. In addition to detection of risk factors in children, these findings can also lead to recognition of occult or clinical disease in other members of the family. The child therefore becomes a source of case finding for other members of the family. The role of the physician who treats children or the entire family unit is a vital one for rearing upcoming generations with new and better health habits.

Role of Exercise

Exercise has recently gained interest as part of a multifaceted intervention program aimed at improving cardiovascular hygiene. Although systematic physical conditioning involving exercise of the endurance type has been considered beneficial to the cardiovascular system, the precise mechanism of such an effect has not been completely clarified.[9] Evaluation of the influence of exercise on the coronary risk factors per se has been difficult. The investigator who undertakes to evaluate the role of physical fitness in altering risk factors often finds that his subjects spontaneously change their habits of smoking, recreation, sleep and other routines that singly or together affect the risk factors as a whole. It is therefore difficult to separate the direct effect of the exercise program from the commonly associated subtle changes in living patterns.

Our studies[10] reveal relatively small effects of exercise training on coronary risk factors. For example, although measurements of skin fold thickness indicating a decrease in fat and an increase in lean body mass, serum cholesterol decreases only 3 to 5 percent and diastolic blood pressure is reduced only 6 to 8 percent. Alteration of risk factors by exercise in other studies[9,11] also indicates that even when these changes are statistically significant, their magnitude is modest. In addition to lack of data indicating that exercise has a major effect on known coronary risk factors, there is no firm evidence that it alters atherogenesis or enhances the coronary collateral circulation. However, it has been suggested that augmented diameter of the vessels of the native coronary circulation may result from exercise.[9] Atherosclerosis would thus be less consequential and its effects delayed.

The beneficial effects of exercise in patients with ischemic heart disease, for example, decreased angina pectoris and increased functional capacity, appear to be closely related to major alterations in the cardiocirculatory response to exercise of the endurance type. Thus, the trained state is associated with a reduced heart rate and, commonly, a reduced blood pressure at any given level of exercise.[12] Increased oxygen extraction and other metabolic adaptations by skeletal muscle are associated phenomena[13] that allow similar external performance at a reduced level of cardiac activity. The result is decreased mechanical effort of the heart and thereby reduced myocardial oxygen consumption.[14]

Thus, exercise may exert important effects on the cardiovascular system independent of any influence on coronary risk factors. It is suggested that exercise may be operative in coronary heart disease by (1) decreasing the clinical manifestations of atherosclerosis in the young, and (2) enhancing individual adaptation to atherosclerosis once the disease is clinically established.[15]

New Approaches to Exercise Programs

If it is accepted that early control of hypertension and adoption of attitudes and behavior leading to altered diet, nonsmoking and avoidance of a time-oriented competitive stress pattern are important in the prevention of premature atherosclerosis beginning early in life,[16] then we should also alter exercise patterns and physical activity habits in children to achieve the most beneficial cardiovascular effects. Activity programs for children should emphasize cardiovascular endurance fitness rather than the conventional athletic games, which are contests of skill and agility and have little positive effect on the cardiovascular system. Activities that children can learn and continue throughout life such as hiking, walking, swimming, jogging, cycling, rowing, folk dancing, square dancing and other activities of the continuing endurance type should be fostered. It is important to recognize that competitive sports do not necessarily produce physical fitness and that children as well as adults should be physically fit first before engaging in sports.

Physical activity appears to be protective only when it operates above a certain threshold level, that is, a level at least 70 to 75 percent of a person's work capacity.[9] Thus, we need new games that are continual and rhythmic and enjoyable and also require enough work to increase cardiovascular endurance. These activities should begin early in the school years, certainly by the first grade. Most elementary schoolyard games are largely passive with short bursts of activity. Activity that is vigorous and imaginative with running, jumping and climbing would be more constructive. Rhythmic, continual group exercises to music and group gymnastics can also be utilized. Schoolyards need jumping pits, horizontal ladders, obstacle courses, balance beams, large ropes to swing on and large areas for running. Changes are re-

quired in the usual sterile playground consisting of some swings, a softball area and a jungle gym. These should be replaced with innovative, interesting and challenging types of programs and equipment that can contribute to the development of the cardiovascular system in a protective way. Competitive sports should be deemphasized and lifelong physical activity emphasized.

New concepts of recreation demanding less participation of the spectator type and more active involvement are required. We need to encourage and provide facilities for family cycling, hiking, skiing, water activities and winter recreation. In other words, family fitness should become a way of life.

Education

How can these changes be brought about? 1. Education is of prime importance. Not only should there be an emphasis on health education in the schools but public education through the media and community groups is necessary in a consistent effort to effect desirable changes for all ages.

2. There is a need for a new image of health and for new health education. The past emphasis has been primarily on knowledge concerning health problems in the belief that such knowledge will affect behavior. It is now apparent that at least equal attention must be given to influencing attitudes and behavior. It is time to stop discussing data in our school and community programs and to focus on changing behavior. This approach, known as behavior modification,[17] is based on principles of learning. It assumes that if a maladaptive behavior is learned, it can be retrained or replaced with a more adaptive one. Even if a behavior is originally determined by genetic or physiologic factors, it can be altered and shaped to be adaptive.

3. There is a need for comprehensive school health education beginning at the elementary level. The health education programs in secondary schools reach children too late. Proper health habits must begin long before the high school level. Most school health education at the elementary level lacks professional leadership and is largely ineffective. Enlightened physicians must play an active role in directing health education in the schools.

4. The most important need is for physicians to become more actively engaged in preventive programs. Physicians should be leaders in primary prevention. Some of the energy and resources of medicine now directed toward the treatment of the disease itself must be aimed at primary prevention.

5. Trained paramedical personnel should be developed to aid the physician in promoting fitness and healthful behavior patterns.

The potential benefits of a comprehensive program directed toward improving cardiovascular health are indeed monumental. The lack of significant, associated disadvantages further emphasizes its rationale and virtue.

Physical Fitness Programs for Adults

KARL G. STOEDEFALKE, PhD

University Park, Pennsylvania

The sedentary habits, occupational stresses and high caloric intake of adults have spurred an interest in physical exercise. Participation in some form of physical activity is necessary to maintain acceptable levels of muscular strength, range of motion of the joints, and endurance. Ideally, each person over the age of 35 years should have a progressive exercise test administered by a physician before undertaking an exercise program. An exercise prescription must take into account the type of activity, intensity of training, frequency of participation and duration of each exercise session. Both an understanding of exercise physiology and a knowledge of exercise programs are essential to sound patient counseling and management.

In a recent national physical fitness survey conducted for the President's Council on Physical Fitness and Sports,[1] 3,875 men and women over the age of 22 years were interviewed. The results indicated that 55 percent of adult Americans, 60 million persons, engage in some form of exercise. Of these 60 million it is estimated that 44 million walk, 18 million bicycle, 14 million swim, 14 million do some type of calisthenics and 6.5 million jog. Many active adults participate in more than one form of exercise.

Although more than half of adult Americans engage in some physical activity, many are not physically educated. They must be helped to make intelligent decisions on the selection of physical activities. And they must be informed about the importance of the frequency of participation, the duration of activity sessions, as well as the intensity of the energy expenditure during exercise. Frequency, duration and intensity and type of exercise are the key words in fitness programs for adults.

Research has provided the scientific basis for exercise decisions: frequency, duration and intensity. It is a matter of time before this information is translated and written in meaningful terms for the general public. In the meantime the American adult relies on the guidance of physicians and physical educators and directors. All too often he does not seek counsel. He relies on past experience and initiates an exercise program on his own. The activity he selects and the intensity of his effort may result in unnecessary pain and discomfort. Sometimes sudden death occurs. This is a high price to pay for an honest attempt to achieve physical fitness.

Programs of physical fitness are available to the public through government publications and the popular press. The books and pamphlets are attractively presented and read by millions of Americans. Each publication has its own special way of convincing adults to do something about the "middle-age troika": weak musculature (especially of the abdomen), lack of flexibility and low endurance capability. The reader has his choice among programs whose requirements range from a few minutes of daily activity to 60 minutes of exercise a day, 6 days a week. Fortunately, each publication also recommends

that the reader consult his personal physician before beginning an exercise program. Accordingly, the intent of this paper is to provide the physician with an understanding of the principles of exercise programs that will enable him to provide intelligent counsel to his patient.

Motivation

Adults decide to exercise for a variety of reasons—health, recreation or relaxation, opportunities for social contact or factors related to personal image and self-esteem. Many Americans believe that exercise is "good for you" and, if performed regularly, will confer health benefits. Some believe that exercise controls body weight. Others maintain that exercise strikes the balance between work and play or serves as a vehicle to ameliorate tensions and frustrations. Man is a social being. Exercise programs, sport and games present an opportunity to meet others with similar interests. A reason for exercise may be to achieve a feeling of euphoria, a feeling that is difficult to quantify or explain. All of these reasons are valid and have one thing in common: They are endogenous. The final and conclusive reason for exercise is the physician's recommendation that if the patient doesn't begin to change his life style and become physically active he may soon have serious medical problems. A previously sedentary adult will benefit from an exercise program if he is motivated. Exercise leaders and physicians must allow for differences in attitude toward exercise and prescribe programs that meet individual needs. A man's adherence to an exercise program depends almost entirely on his motivation.

Scientific Evaluations

Table I, developed by Hodgson,[10] presents data on maximal oxygen uptake ($\dot{V}O_2$ max) for moderately active men aged 20 to 59 years. The equation ($\dot{V}O_2$ max, ml/kg per min = 61.6 − 0.44 Age) used to construct Table I was developed from mean values reported in nine studies with a total of 302 men plus data from lumberjacks referred to by Andersen.[11] Like these moderately active men, sedentary men, after a period of conditioning, showed a similar reduction in $\dot{V}O_2$ max with age, but their data were not included. In these studies, moderately active was defined to include men who were former athletes or were active by occupation or recreation. Table I provides the physician with objective data against which he can measure his patient's capabilities. A reliable assessment of performance capability is a critical aspect of an exercise prescription. A laboratory assessment of aerobic capacity provides the physician with the objective criteria needed for diagnosis and recommendation.

Types of Programs

It has been well established that there is a high degree of specificity in physical fitness programs. Fitness programs can be designed for specific goals. If the desired goal of the exercise program is muscular strength, strength-producing types of activities (dynamic weight training; static isometric exercise) will result in higher levels of strength during performance. If increased range of motion of the joints is the desired goal, exercise programs can be designed to increase a subject's flexibility. If cardiorespiratory endurance is the goal, programs of aerobic training that include a wide variety of human movements will result in increased endurance capability. Many agency-sponsored programs (Jewish Community Centers, Young Men's Christian Association) attempt to incorporate all three goals in an exercise session: strength, flexibility and endurance. Published programs for the general public may emphasize the importance of only one factor. All three factors are important, but priority and emphasis should be placed on the cardiorespiratory organs. Aging man needs a frequent training stimulus to the heart and circulatory system.

Ideally a physical fitness training session should consist of a warm-up period, an endurance phase, a game (optional) and a cooling down period.

Warm-up (3 to 5 minutes): The warm-up period is recommended to prepare the body for sustained activity. A warm-up period increases blood flow and stretches postural muscles. It is a period of adaptation. Rhythmic movements of the segments and

trunk are precautions against the occurrence of skeletal muscle strain.

Endurance (15 to 30 minutes): The training of the oxygen transport system is essential. The cardiopulmonary system should be stressed by activities of graduated intensity. The intensity of work loads is changed when adaptation occurs. Table II lists some typical activities that improve endurance of performance.

Games, fun (10 to 15 minutes): A game is defined as any competition in which the object is to gain a temporary advantage over one's opponent. In prophylactic exercise programs the games portion has a single goal—fun. Participation in games should be physical self-expression for its own sake. Winning or losing should be secondary to play. Men who are symptomatic or at risk of coronary disease need creative outlets for their energy expenditure. The need to win or to be first is often the reason why a man becomes an early candidate for myocardial infarction. Games with few rules and many participants are ideally suited for a structured or group exercise program.

Cooling down (3 to 5 minutes): At the completion of an exercise session some time should be devoted to the cooling down process. Exercise raises core temperature and increases heart rate and arterial pressures. The last few minutes of exercise should include gross body movements. The intensity of these movements should be gradually decreased. Activities that maintain or improve range of motion of the joints are desirable.

Exercise Studies of Middle-Aged Men

Since 1964, nineteen studies have been published on the effect of physical training on maximal aerobic power.[12–27] These studies ranged from 5 weeks to 2 years in duration; the subjects, all male, ranged in age from 20 to 60 years and exercised 2 to 6 days a week. All 19 studies reported increases in maximal oxygen uptake between the initial and final testing sessions. A 6 percent increase was reported by Wilmore et al.[23]; Cureton and Phillips[27] reported an increase of 38 percent. Thirteen of the 19 studies reported increases in aerobic power in excess of 15 percent of the base-line measures.

The subjects of these studies participated in a variety of aerobic training activities including calisthenics, jogging, running, walking, bench-stepping, bicycling and swimming. Some programs included games of handball, paddleball or volleyball. The results indicate that aerobic power increases with training and that this training effect occurs at all age levels. The degree of improvement depends upon the type of activity, the frequency of training and the intensity of the exercise sessions.

Frequency: Research has not determined how frequently exercise should be performed for optimal cardiorespiratory improvement. An acceptable recommendation is three times weekly. This schedule permits an adequate period of recovery between activity sessions.

TABLE II

Activities That Improve Endurance of Performance

1. Walking
2. Jogging
   a. In place
   b. Moving
3. Running
4. Cycling
5. Skiing
   a. Alpine
   b. Nordic
6. Swimming
7. Rope skipping
8. Ice skating
9. Roller skating
10. Rowing
11. Bench or stair climbing

Intensity: The intensity of training is critical to improvement in aerobic capacity. The best estimate at this time is that an intensity of 70 percent of a person's maximal aerobic power is sufficient to afford cardiorespiratory gains. Activity performed at a greater intensity produces change, but of a much smaller magnitude. Determining the appropriate intensity of the activity for each individual depends upon the base-line measures obtained during a progressive exercise test. Training regimens can be based on the concept of METS (1 MET = 3.5 ml oxygen/kg per min) or target heart rates. The monitoring of heart rates during activity sessions is important. In an asymptomatic adult, activity heart rates during the endurance phase of training are maintained at levels of 120 to 160 beats/min.

Duration: Cardiorespiratory benefits occur when an exercise session is more than 10 minutes in duration. In programs of prevention, intervention and rehabilitation, sessions are usually 20 to 45 minutes long.

Research indicates that adults reach an optimal training level some time after 20 to 30 weeks of regular physical activity. At approximately 6 months, maximal aerobic power gains tend to plateau. The degree of improvement is related to the state of deconditioning; that is, the lower the level of initial performance capability, the greater the expected improvement.

Adherence: Improvement in endurance, strength and range of joint motion requires adherence to an exercise regimen. Problems of muscle or joint soreness occur frequently. Foot, ankle, knee and back pains are not only irritants but seriously impair attendance and participation. These problems can be minimized if the introduction to an exercise program is gradual. Moderation is important. Occasionally a man reports that his interest has waned because of the monotony of the exercise regimen. Other dropouts from physical activity programs report that the time required for exercise deprived them of time spent on the job or with their family. Complaints of orthopedic problems or monotony can be avoided by skillful exercise leaders and informed physicians who

counsel their patients in the proper selection of activity. The time spent away from one's job or family cannot be avoided, but it is not a large price to pay for improvement in health status.

No one is ever too old to have a good time. Exercise should be a pleasant experience. A preoccupation with distance, number of repetitions or a stop watch may provide incentives but is of secondary importance in adult fitness programs. The primary emphasis should be on participating in activities that are safe and enjoyable. When this goal is achieved, people will sustain and adhere to their exercise commitment.

Conclusions

There is a national awareness of the need to improve the physical fitness of adults. Physical activity of a progressive nature produces functional changes. Through exercise, people can increase their endurance capabilities, muscular strength and range of motion of the joints. A progressive exercise test that includes monitoring of the subject's electrocardiogram and arterial blood pressures is the objective assessment necessary to the exercise prescription. Programs should be designed or recommended to meet individual needs. Special attention should be paid to gradual orientation to the exercise regimen. Initially low levels of energy expenditure are desirable. The concepts of intensity, frequency and duration are important. Adaptation to the stress of exercise requires time. Every effort should be made to support the adult in his participation. Successful patient management rests with the cooperative effort and communication of a patient, his physician and the leader of physical activity.

Before a physician recommends an individual exercise regimen or group program, he should carefully evaluate it. Answers to the following questions are important to his evaluation: Does the program allow for individual differences? Is the subject gradually eased into the exercise program? Are the exercise leaders competent? Is adequate supervision available in programs where participants are at high risk? What factors determine the intensity of the exercise session? Are allowances made for participants who have special medical problems (arthritis, emphysema, diabetes, asthma)? What are the avenues for communication and feedback on the patient's progress?

The assessment of human performance is a science. Individually prescribing activity is an art.

Acknowledgment

I acknowledge the assistance of James Hodgson, Mitchell McKirnan and Gale Miller. Special thanks to Cal Shearburn for his efforts in computing the table of aerobic power estimations.

TRACK
a new
approach
in angina
pectoris...

Inderal®

Brand of

propranolol hydrochloride

beyond conventional measures and nitroglycerin

INDERAL, through a new mechanism, provides a unique approach in the management of patients with moderate to severe angina pectoris unresponsive to weight control, cessation of smoking, rest, sublingual nitroglycerin, and avoidance of precipitating factors. INDERAL should not be used in patients in whom anginal attacks occur only with considerable effort or infrequent precipitating circumstances.

decrease in anginal attacks and need for nitroglycerin

In 29[1-29] of 30[1-30] controlled clinical trials, INDERAL was found to reduce the incidence of anginal pain and the consumption of nitroglycerin. In 24[1-9,11-15,17,18,20-24,26,27,30] of these studies, it was possible to determine the proportion of patients responding to treatment; approximately 75 percent of the patients had less pain and used less nitroglycerin when taking INDERAL than when taking a placebo. Of the 29 studies reporting effectiveness with INDERAL, results were deemed statistically significant in 19,[1-19] not statistically significant in 2,[20,21] and the statistical significance was not given in 8.[22-29] In these and 3 other studies,[31-33] the effectiveness of INDERAL was demonstrated both clinically and by objective laboratory measurements. One study[30] reported propranolol not effective. Altogether, these clinical studies[1-33] covered 746 patients.

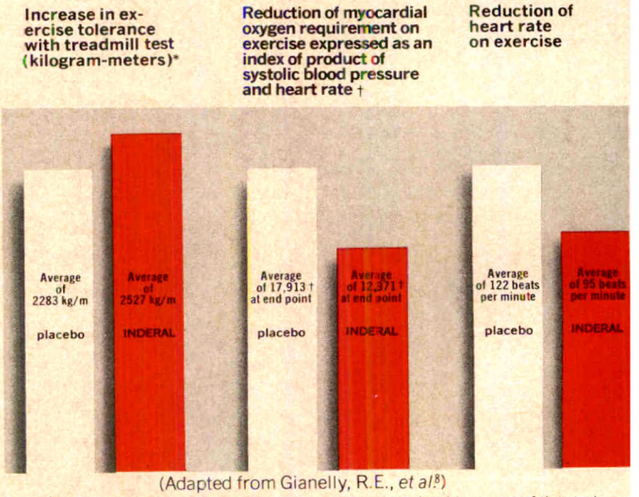
improved exercise tolerance

In 17 controlled trials dealing with exercise tolerance, INDERAL was found to be effective in 14[2,8,10,12,13,15,16,18,22,23,25,27,28,32] and not in 3.[3,29,30] In 8[2,8,10,12,15,16,18,32] of these, the improvement was statistically significant, in 6[13,22,23,25,27,28] the significance was not given.

objective proof of effectiveness

clinical results with 160 mg. Inderal (propranolol hydrochloride) daily in 19 patients

In a double-blind study, the effect of INDERAL on exercise tolerance was examined by Gianelly and associates.[8] It was concluded that in responsive patients, INDERAL, by reducing cardiac work, tends to bring into balance myocardial oxygen supply and need, and increases exercise tolerance.



(Adapted from Gianelly, R.E., *et al*[8])

*Incomplete data on one patient reduced the number to 18 for this aspect of the study.

In a double-blind crossover study of 19 patients with a typical history of angina and a positive Master 2-step test, the effects of INDERAL on exercise tolerance were correlated with cardiovascular physiologic effects. The patients, ranging in age from 38 to 65 years, received either placebo or 160 mg. INDERAL daily in 4 divided doses for 4 weeks. Exercise tolerance was assessed using a treadmill.

in the management of moderate to severe angina pectoris

works to decrease myocardial oxygen demand and prevent oxygen deficit in responsive patients

When physical or psychological stress increases beta-adrenergic stimulation of the heart, oxygen demand may exceed capacity for oxygen delivery in a coronary circulation compromised by atherosclerosis.

INDERAL (propranolol hydrochloride)—through its beta-adrenergic blocking action—provides a unique approach. By specifically competing with catecholamines for available myocardial beta-receptor sites, INDERAL can reduce sympathetically induced increases in heart rate, systolic blood pressure, and velocity of contraction during exercise or stress—and thus decrease the oxygen requirements of the heart. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta-adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to the decreased oxygen requirement.

for maximum effect, dosage should be titrated and individualized

The average optimum dosage of INDERAL appears to be 160 mg. per day, although individuals may respond at any dosage level. Starting with 10-20 mg. 3 or 4 times daily, before meals and at bedtime, dosage should be gradually increased at 3 to 7 day intervals until optimum response is obtained. Doses higher than the average optimum dosage of 160 mg. may be required; however, the value and safety of dosage exceeding 320 mg. per day have not been established.

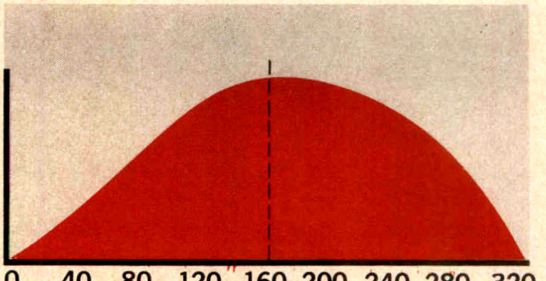
If treatment is to be discontinued, it is recommended that withdrawal be gradual over a period of several weeks. (See PRECAUTIONS.)

Special caution should be observed in patients with heart block or a history of congestive heart failure. (See CONTRAINDICATIONS and WARNINGS.)

Good medical practice dictates that INDERAL should not be continued unless there is reduced pain or increased work capacity. Treatment should be carefully monitored.

INDERAL will not interfere with the cardiac action of sublingual nitroglycerin, or cardiotonic agents such as digitalis.

average optimum daily dosage is 160 mg.



Clinical experience as reported in controlled studies has shown that the average optimum dosage appears to be 160 mg. per day. However, dosage must be individualized as some patients may obtain maximum response at a dosage level lower than 160 mg. daily, and others may require a dosage up to 320 mg. daily. The value and safety of daily doses of more than 320 mg. have not been established. (See DOSAGE AND ADMINISTRATION and OVERDOSAGE OR EXAGGERATED RESPONSE)

USE OF **INDERAL®** /ANGINA PECTORIS

BRIEF SUMMARY

(For full prescribing information, see package circular.)

Inderal®

Brand of propranolol hydrochloride

A beta-adrenergic blocking agent

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

ACTIONS: INDERAL is a beta-adrenergic receptor blocking drug, possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available beta receptor sites. When access to beta receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential and depresses cardiac function.

Propranolol is almost completely absorbed from the gastrointestinal tract, but a portion is immediately bound by the liver. Peak effect occurs in one to one and one-half hours. The biologic half-life is approximately two to three hours. There is no simple correlation between dose or plasma level and therapeutic effect, and the dose-sensitivity range as observed in clinical practice is wide. The principal reason for this is that sympathetic tone varies widely between individuals. Since there is no reliable test to estimate sympathetic tone or to determine whether total beta blockade has been achieved, proper dosage requires titration.

Beta receptor blockade is useful in conditions in which, because of pathologic or functional changes, sympathetic activity is excessive or inappropriate and detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

The proper objective of beta blockade therapy is to decrease adverse sympathetic stimulation but not to the degree that may impair necessary sympathetic support or vital functional balances.

Propranolol exerts its antiarrhythmic effects in concentrations associated with beta-adrenergi blockade and this appears to be its principal antiarrhythmic mechanism of action. The membrane effect also plays a role, particularly, some authorities believe, in digitalis-induced arrhythmias. Beta-adrenergic blockade is of unique importance in the management of arrhythmias due to increased levels of circulating catecholamines or enhanced sensitivity of the heart to catecholamines (arrhythmias associated with pheochromocytoma, thyro-

toxicosis, exercise).

Propranolol may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta-adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to decreased oxygen requirement.

INDICATIONS: *Angina Pectoris Due to Coronary Atherosclerosis.* The initial treatment of angina pectoris involves weight control, rest, cessation of smoking, use of sublingual nitroglycerin, and avoidance of precipitating circumstances. INDERAL (propranolol hydrochloride) is indicated in selected patients with moderate to severe angina pectoris who have not responded to these conventional measures. Propranolol should not be used in patients with angina which occurs only with considerable effort or with infrequent precipatating factors.

INDERAL exerts both favorable and unfavorable effects, the preponderance of which may be beneficial. (See ACTIONS Section.) INDERAL should not be continued unless there is reduced pain or increased work capacity.

Because of the potential for adverse results, treatment should be carefully monitored. The patient should also be reevaluated periodically since the dosage requirement and the need to continue INDERAL may be altered by clinical exacerbations or remissions. (See DOSAGE AND ADMINISTRATION.)

Additional studies of the effects of INDERAL in angina pectoris patients are in progress to better evaluate and define the proper role of INDERAL in this condition.

CONTRAINDICATIONS: INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS: CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.* that of supporting the strength of myocardial contractions). However, the inotropic action of digitalis may be reduced by INDERAL's opposite inotropic effect. The effect of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized, and the response observed closely: (a) if cardiac failure continues, INDERAL therapy must be immediately withdrawn; (b) if tachyarrhythmia is being controlled, patients should be maintained on combined dosage and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg. propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL (propranolol hydrochloride) should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.* isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.* CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. Especially important with labile diabetics.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit.

PRECAUTIONS: Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

When discontinuance of chronically administered INDERAL is planned, the dosage should be gradually reduced over a period of several weeks and the patient should continue to be carefully monitored. There have been reports of myocardial infarction occurring in angina pectoris patients following *abrupt* discontinuation of INDERAL therapy.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS: *Cardiovascular:* bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress

Respiratory: bronchospasm

Hematologic: agranulocytosis, non-thrombocytopenic purpura, thrombocytopenic purpura

Miscellaneous: reversible alopecia

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase

DOSAGE AND ADMINISTRATION: The oral route of administration is preferred.

ORAL

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 10-20 mg. three or four times daily, before meals and at bedtime, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg. per day. The value and safety of dosage exceeding 320 mg. per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of several weeks. (See PRECAUTIONS.)

PEDIATRIC DOSAGE

At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

OVERDOSAGE OR EXAGGERATED RESPONSE: IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg.): IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS

HYPOTENSION—VASOPRESSORS, *e.g.* LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE.)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE

HOW SUPPLIED

INDERAL
(propranolol hydrochloride)

TABLETS

No. 461—Each tablet contains 10 mg. of propranolol hydrochloride, in bottles of 100 and 1,000.

No. 464—Each tablet contains 40 mg. of propranolol hydrochloride, in bottles of 100 and 1,000.

INJECTABLE

No. 3265—Each cc. contains 1 mg. of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 cc. ampuls in boxes of 10.

hypertension puzzle

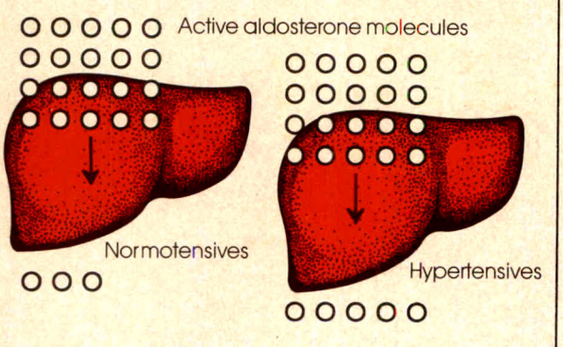
The liver metabolizes significantly less aldosterone in hypertensives than in normotensives.[1,2]

A significantly decreased hepatic MCR (metabolic clearance rate) of aldosterone, without significantly decreased SR (secretion rate), was demonstrated in approximately 90 percent of a group of 56 patients with benign essential hypertension.[1]

Thus "Failure of the aldosterone SR to fully adapt to the decrease in MCR may be responsible for a relative state of hyperaldosteronism in many patients with BEH [benign essential hypertension], even when the secretion and excretion rates are within normal range.

"It is conceivable that it is the mineralocorticoid [aldosterone] excess that is leading to an increase of sodium content in the arteriolar wall and the hypertensive process itself, in many patients with BEH."[2]

Metabolic clearance of aldosterone in hypertensives and in normotensives*



*Schematic representation

To help control the aldosterone factor in essential hypertension

Aldactazide®

(spironolactone 25 mg./hydrochlorothiazide 25 mg.)

- Spironolactone blocks the pressor effect of aldosterone at the arteriole,[3-5] and exerts natriuretic action in the distal renal tubule.
- Hydrochlorothiazide exerts additive antihypertensive effect through its action at a different renal site.
- Aldactazide helps maintain potassium balance—without the need for potassium supplements—because the potassium-sparing action of spironolactone offsets the potassium-losing effect of hydrochlorothiazide.

See following page for brief summary.

To help control the aldosterone factor in essential hypertension

Aldactazide®

(spironolactone 25 mg./hydrochlorothiazide 25 mg.)

Indications—Hypertension; edema or ascites of congestive heart failure, cirrhosis of the liver and the nephrotic syndrome; idiopathic edema. Some patients with malignant effusion may benefit from Aldactazide therapy.

Contraindications—Acute renal insufficiency, rapidly progressing impairment of the renal function. Anuria; sensitivity to thiazides or other sulfonamide-derived drugs. Probably contraindicated in acute or severe hepatic failure.

Warnings—Fixed-dose combination drugs are not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Potassium supplementation is recommended only in exceptional instances, but may be considered when a glucocorticoid is also given. Utilize normal dietary sources of potassium if possible when potassium supplementation is necessary. If enteric-coated potassium is used be alert to the possible development of hemorrhagic, stenotic, ulcerated or perforated small-bowel lesions; deaths have occurred. The possibility of exacerbation or activation of systemic lupus erythematosus by sulfonamide derivatives, including thiazides, has been reported.

Administer thiazides with caution to pregnant or lactating patients. Adverse reactions which may occur in the adult (hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism, etc.) may possibly occur in the newborn, since thiazides cross the placental barrier and may also appear in breast milk.

Precautions—Consider the possibility of fluid and electrolyte imbalance. Serum and urine electrolyte determinations are particularly important in patients with excessive vomiting or in those receiving fluids parenterally. Medications such as digitalis may also influence serum electrolytes. Warning signs of possible fluid and electrolyte imbalance are: dryness of the mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains, cramps or fatigue, hypotension, oliguria, tachycardia, gastrointestinal symptoms. Hypokalemia may develop with brisk diuresis in severe cirrhosis or during the concomitant use of glucocorticoids or ACTH. Inadequate oral electrolyte intake contributes to hypokalemia. Hypokalemia may cause signs of digitalis intoxication with previously tolerated doses of digitalis.

Give Aldactazide cautiously to patients with severe liver disease since thiazides can precipitate hepatic coma; discontinue if mental confusion increases. Consider also other factors that may precipitate hepatic coma, including blood in the gastrointestinal tract or preexistent potassium depletion. Reversible elevation of NPN and BUN may occur in some patients receiving Aldactazide. The most common electrolyte disturbance is dilutional hyponatremia which requires appropriate corrective measures. A true low-salt syndrome is rare; discontinue Aldactazide and administer sodium for this condition.

Although rare, the most potentially serious electrolyte disturbance is hyperkalemia; if this occurs discontinue Aldactazide and restrict potassium intake. Rarely, fatality due to hyperkalemia has been reported. Hyperkalemia is more likely to occur in severely ill patients with relatively small urine output or in patients receiving supplemental potassium; determine serum electrolytes frequently in such patients. Consider the possibility of hyperuricemia or a decrease in tolerance to glucose.

Patients with severely resistant edema may have an increased diuretic response following the addition of a potent glucocorticoid, such as 15 to 20 mg. of prednisone daily, to Aldactazide therapy. Supplemental potassium will usually be necessary in such patients and the usual precautions with glucocorticoids are necessary. Use caution if regional or general anesthesia is necessary since Aldactazide reduces vascular responsiveness to norepinephrine in such patients. Thiazides may increase responsiveness to tubocurarine. The antihypertensive effects of hydrochlorothiazide may be enhanced in patients who have undergone sympathectomy.

Pathologic changes in the parathyroid glands, with hypercalcemia and hypophosphatemia, have been observed in a few patients on prolonged thiazide therapy.

Thiazides may increase serum PBI levels without signs of thyroid disturbance.

Adverse Reactions reported with *spironolactone* use: Drowsiness and lethargy, mental confusion, diarrhea and other gastrointestinal symptoms, mild androgenic manifestations (including hirsutism, menstrual irregularity, deepening of the voice), gynecomastia, inability to achieve or to maintain erection, headache, maculopapular or erythematous cutaneous eruptions, urticaria, drug fever, ataxia.

Adverse reactions reported with *thiazide* use: purpura, thrombocytopenia, leukopenia, agranulocytosis, gastrointestinal disorders (anorexia, nausea, vomiting, diarrhea, abdominal cramps), rash, pruritus, paresthesia, acute pancreatitis, jaundice, dizziness, vertigo, headache, xanthopsia, photosensitivity, urticaria, necrotizing angiitis, aplastic anemia, orthostatic hypotension, muscle spasm, weakness, restlessness. Reduce dosage or withdraw drug whenever adverse reactions are moderate or severe.

Dosage and Administration—Dosage should be determined by individual titration. *For essential hypertension* the daily *adult* dosage is two to four tablets in divided doses; continue treatment for two weeks or longer. Adjust the dosage according to the response of the patient. Reduce the dosage of other antihypertensive agents, particularly ganglionic blocking agents, by 50 percent since Aldactazide potentiates the action of such drugs. *For edema, ascites or effusion in adults* the average dosage is one tablet 4 times daily; dosage may range from 1 to 8 tablets daily in divided doses. The daily dosage of Aldactazide *in children* should provide 0.75 to 1.5 mg. of Aldactone® (spironolactone) per pound of body weight.

Comparative Response to Isometric (Static) and Dynamic Exercise Tests in Coronary Disease

JEAN-CLAUDE HAISSLY, MD
ROGER MESSIN, MD
SERGE DEGRE, MD
POL VANDERMOTEN, MD
BETTY DEMARET, MD
HENRI DENOLIN, MD, FACC

Brussels, Belgium

Forty-six patients with arteriosclerotic heart disease manifested significant electrocardiographic changes (accompanied by angina in 35) during maximal exercise testing. These patients subsequently performed isometric exercise at levels representing various percentages of maximal voluntary contraction. Twenty-two patients also performed combined isometric and submaximal dynamic exercise. The prevalence rate of S–T segment changes during isolated isometric exercise depended on the percent of maximal voluntary contraction applied but was far lower than the rate observed during maximal dynamic exercise. Angina seldom occurred. Manifestations of coronary insufficiency appeared more often during combined submaximal dynamic and isometric exercise than during isolated isometric testing.

Aortic pressure was measured in eight cases. Tension-time index and pressure-heart rate product were lower when maximal dynamic exercise was stopped owing to coronary insufficiency than at the end of isolated isometric exercise or combined submaximal dynamic and isometric exercise. However, the latter two tests produced fewer ischemic manifestations. The reasons for these discrepancies are discussed. We conclude that isometric exercise tests are unsuitable for diagnosing coronary insufficiency.

Although isometric exercise is a common everyday activity, its hemodynamic effects have not been extensively studied. In normal subjects, the increases in heart rate and blood pressure produced by isometric exercise depend on the percent of maximal voluntary contraction exerted independent of the muscle group involved. At levels greater than 15 to 20 percent of maximal voluntary contraction, hemodynamic response increases linearly until the end of the exercise, greater loads producing greater changes and rapid muscular fatigue.[1] Isometric stress testing may be hampered by the lack of steady state hemodynamic measurements, poor patient cooperation and the subjective nature of determining maximal voluntary contraction, but it is easily and quickly performed, and hemodynamic values return to resting levels shortly after muscular relaxation.

When two isometric loads are applied either simultaneously[2] or successively (personal observation, J-CH), heart rate and blood pressure responses at the end of the test depend on the intensity of the greater and second loads, respectively. The response to combined dynamic and isometric exercise is greater than the response to either test alone.[2]

In this study we investigated the comparative influence of isometric and dynamic exercise on the symptoms, electrocardiogram, tension-time index and pressure-heart rate product of patients with arteriosclerotic heart disease.

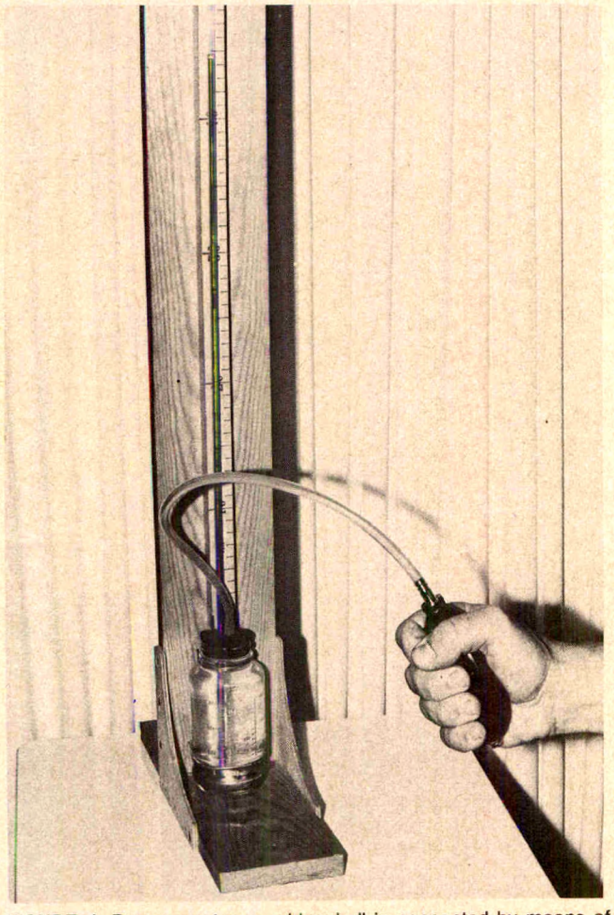

FIGURE 1. Dynamometer: a rubber ball is connected by means of semirigid tubing to a closed chamber, the lower third of which contains mercury. The lower end of a vertically fixed glass tube (inner diameter 2 mm) is placed into the mercury. The upper two thirds of the chamber, rubber ball and tubing are filled with water. When the rubber ball is pressed, mercury is pushed into the glass tube. The small bore of the tube results in a small displacement of mercury volume, thus avoiding any significant dynamic component.

Material and Methods

Material

The study group comprised 46 volunteer male outpatients, aged 36 to 66 years, with arteriosclerotic heart disease. Confirmation of the diagnosis was based on the presence of electrocardiographic signs of old infarction or typical symptoms of angina pectoris. During dynamic exercise testing all patients showed typical S–T segment changes and 35 had angina. No patient had signs of ventricular aneurysm, heart failure, angina, significant arrhythmias or conduction disturbances at rest.

Procedure

Dynamic exercise was performed with patients seated on an electrically braked bicycle ergometer (Elema); loads were increased by 25 watts every 5 minutes until the electrocardiogram showed a horizontal or downsloping S–T segment depression of at least 0.2 mv.[3,4]

Isometric exercise was performed alone or in combination with dynamic exercise. For this purpose we utilized sustained contraction of a handgrip calibrated with a mercury manometer; the tubing had a small bore to avoid any significant dynamic component (Fig. 1). Patients were requested to breathe freely while maintaining their grasp on the handgrip until they experienced exhaustion at 30, 50, 70 or 90 percent of maximal voluntary contraction. The latter was defined as the mean value between the two most powerful contractions in three successive trials. Every patient sustained two different submaximal isometric exercise levels. Mean test durations were, respectively, 265, 125, 63 and 31 seconds at the 30, 50, 70 and 90 percent levels.

Twenty-two patients whose electrocardiogram did not change during isometric exercise were submitted to a dynamic load 25 to 50 watts less than the individual maximal work load; isometric exercise (at 30 or 50 percent of maximal voluntary contraction) was added at the start of the sixth minute of exercise.

The electrocardiogram (leads I, II, V_2 and V_5) was recorded every minute on a four channel Mingograph 34 (Elema). In some patients with angina pectoris a polyethylene catheter (PE 150) was introduced percutaneously through the brachial artery into the ascending aorta and

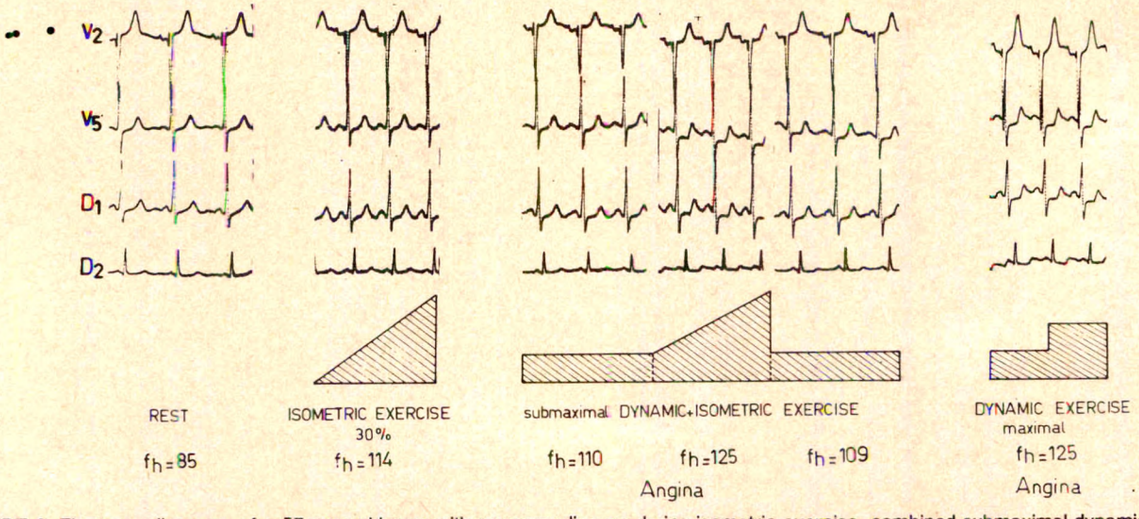

FIGURE 2. Electrocardiograms of a 57 year old man with coronary disease during isometric exercise, combined submaximal dynamic and isometric exercise and maximal dynamic exercise. fh = heart rate.

blood pressure was recorded with a Statham transducer (P23Db), using a Philips amplifier and a Honeywell 1508 Visicorder.

Isometric exercise was performed on the day of the dynamic effort, at least 30 minutes after the electrocardiographic changes disappeared, or several days later. Most patients were tested in the afternoon, 2 or 3 hours after lunch. Patients who underwent intraaortic catheterization performed their exercise in the morning after breakfast, starting with isometric testing and performing dynamic exercise later, at least 30 minutes after the disappearance of electrocardiographic changes.

Results

Heart rate: The increase in heart rate was similar at the end of the four isometric exercise levels performed by 20 patients: 104 ± 3 (standard error of the mean) at 30 percent, 108 ± 3 at 50 percent, 113 ± 3 at 70 percent and 108 ± 4 at 90 percent of maximal voluntary contraction. It was significantly lower ($P < 0.05$ to 0.01) than during maximal dynamic exercise in the corresponding groups (respectively, 120 ± 4, 119 ± 4, 122 ± 4 and 124 ± 5). It was the same after combined maximal dynamic exercise and submaximal dynamic isometric exercise (respectively, 117 ± 4 and 116 ± 4).

Electrocardiogram: S–T segment depression of at least 0.2 mv occurred during maximal dynamic exercise in all 46 patients (and 35 of these patients experienced angina) (Table I). No patient manifested arrhythmias or conduction disturbances. The highest average level attained was 75 watts (range 25 to 125).

During isometric exercise, S–T segment depression was inconstant, occurring in 3 of 20 patients at 30 percent, 7 of 20 at 50 percent and 6 of 20 at 70 percent; no changes were observed at 90 percent of maximal voluntary contraction. These changes usually disappeared within a few seconds after the test was stopped and never occurred during the recovery period. Rare extrasystoles were noted, but no other rhythm disturbances were recorded.

During the combined submaximal dynamic and isometric exercise, S–T segment changes were more frequent, occurring in 15 of 22 cases; in all 15 electrocardiographic changes had not occurred during isolated isometric exercise (Table I). These changes were prolonged, lasting 1 to 8 minutes during the recovery period. Only a few extrasystoles were observed in these patients.

Angina: This symptom appeared during maximal dynamic exercise in 35 of the 46 patients (Table I). Only one of these patients had pain during isometric exercise, at 30 and 50 percent of maximal voluntary contraction. Among 18 patients who had angina during maximal dynamic exercise and no electrocardiographic changes during isometric exercise, 10 had pain during combined submaximal dynamic and isometric exercise. These findings were not due merely to prolongation of submaximal dynamic exercise, because when the latter is maintained after isometric exercise is stopped, pain (and S–T changes) may regress (Fig. 2).

Tension-time index[5] and pressure-heart rate product[6]: These variables were calculated from intraaortic pressure recordings obtained in eight patients who performed maximal dynamic exercise (interrupted by angina), isometric exercise and combined submaximal dynamic and isometric exercise (Tables II and III). Heart rate was lower at the end of isometric exercise than at the end of maximal dynamic exercise (respectively, 108 ± 5 and 114 ± 4), but arterial pressure was significantly greater (respectively, 200 ± 12 and 170 ± 10 mm Hg for systolic pressure, 121 ± 6 and 89 ± 4 mm Hg for diastolic pressure), so that tension-time index and pressure-heart rate product were higher at the end of isometric exercise. The difference is statistically significant for tension-time index (respectively, 4,710 ± 360 and 4,160 ± 280) (Table II). However, all of these patients stopped isometric exercise because of muscular fatigue, and none had angina. During combined submaximal dynamic and isometric exercise, tension-time index and pressure-heart rate product were statistically higher than during maximal dynamic exercise (respectively, 5,200 ± 300 and 4,170 ± 280 for tension-time index, 22,900 ± 1,800 and 19,600 ± 1,400 for pressure-heart rate product) although only five patients experienced angina during the combined dynamic and isometric exercise test (Table III and Fig. 3).

TABLE I

Instances of S–T Segment Changes and Angina During Exercise in Four Groups of 20 Patients and One Group of 22 Patients

	Isometric Exercise (% MVC)				Submaximal Dynamic Plus Isometric Exercise (30 and 50% MVC)
	30	50	70	90	
Patients (no.)	20	20	20	20	22*
S–T depression					
≤0.1 mv	0	3	5	0	0
≥0.2 mv	3	4	2	0	15
Angina†	1‡	1‡	0	0	10
S–T depression ≥0.2 mv during maximal dynamic exercise	20	20	20	20	22
Angina during maximal dynamic exercise	12	15	13	16	18

* None of these patients had electrocardiographic changes during isolated isometric exercise.

† All of these patients had angina during maximal dynamic exercise.

‡ The same patient performed at both 30 and 50 percent of maximal voluntary contraction.

MVC = maximal voluntary contraction.

Discussion

Although isometric exercise tests have been widely used for diagnostic purposes and pathophysiologic

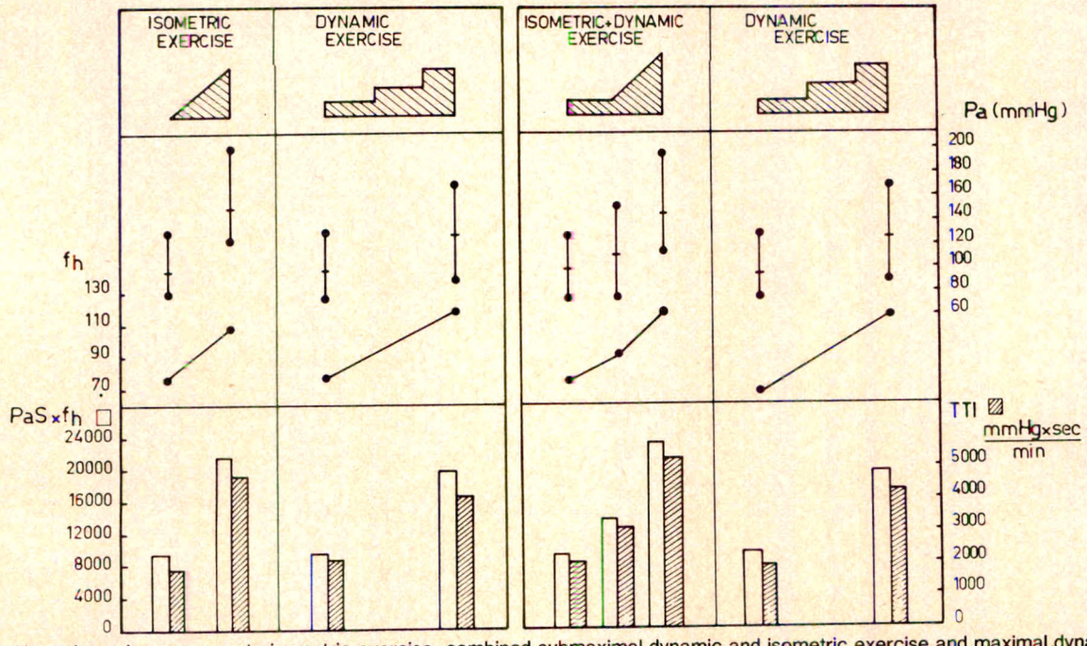

FIGURE 3. Hemodynamic responses to isometric exercise, combined submaximal dynamic and isometric exercise and maximal dynamic exercise in eight patients with angina pectoris (results of Tables II and III). fh = heart rate; Pa = aortic pressure; PaS = systolic aortic pressure; TTI = tension-time index.

TABLE II

Hemodynamic Variables During Isometric and Maximal Dynamic Exercise in Eight Patients with Angina Pectoris*

	Rest	Isometric Exercise	Rest	Maximal Dynamic Exercise
HR	73 ± 3 (7)	108 ± 5 (13)	73 ± 3 (9)	114 ± 4 (10)
APs	131 ± 8 (22)	200 ± 12 (33)	131 ± 8 (24)	170 ± 10 (28)†
APd	78 ± 4 (11)	121 ± 6 (17)	77 ± 3 (10)	89 ± 4 (12)‡
TTI	1,940 ± 140 (400)	4,710 ± 360 (1,020)	2,130 ± 160 (450)	4,160 ± 280 (780)§
APs × HR	9,600 ± 800 (2200)	21,800 ± 1,700 (4,800)	9,600 ± 800 (2,200)	19,400 ± 1,200 (3,500)

Values given are means ± standard error with standard deviation in parenthesis.

APd = diastolic aortic pressure (mm Hg); APs = systolic aortic pressure (mm Hg); HR = heart rate (beats/min); TTI = tension-time index (mm Hg·sec/min).

* Angina always caused the interruption of dynamic testing. No symptoms were caused by isometric exercise. The following variables were significantly higher at the end of the isometric exercise than during maximal dynamic exercise: APs ($P < 0.01$)†; APd ($P < 0.001$)‡ and TTI ($P < 0.05$)§.

TABLE III

Hemodynamic Variables During Submaximal Dynamic Exercise, Combined Dynamic and Isometric Exercise and Maximal Dynamic Exercise in Eight Patients with Angina Pectoris*

	Rest	Submaximal Dynamic Exercise	Submaximal Dynamic + Isometric Exercise	Rest	Maximal Dynamic Exercise
HR	72 ± 5 (13)	90 ± 6 (16)	118 ± 5 (15)	68 ± 3 (10)	113 ± 5 (15)†

* Angina was the cause for interruption in all dynamic tests and in five combined dynamic and isometric tests. The following variables were significantly higher at the end of combined submaximal dynamic and isometric exercise than during maximal dynamic exercise: APd, APs, HR and TTI ($P < 0.05$)†, and APs × HR ($P < 0.01$)‡. Abbreviations as in Table II.

studies[7–12] in valvular heart disease, their value in ischemic heart disease has been controversial. According to Jackson[13] and Siegel et al.[14] they produce S–T segment changes in one third to one fourth of patients. However, Atkins et al.[15] cited significant S–T changes in only 2 of 11 patients, and Kivowitz et al.[12] observed no angina in 13 cases. In our series, typical S–T segment changes during isometric exercise occurred in one third of the patients with a normal resting electrocardiogram, and angina developed in only 1 of the 35 patients. The discrepancies in these findings could be due to differences in intensity of isometric exercise, which ranged from 20 to 100 percent of maximal voluntary contraction in the various series. In our experience, however, the prevalence of S–T changes is similar between 30 and 70 percent of maximal voluntary contraction; at 90 percent the absence of ischemic myocardial manifestations is essentially caused by an excessively short stress tolerance. Probably more important are differences in the criteria of exercise intolerance: During isometric exercise many patients report vague chest pain although they have no S–T changes; such findings may or may not be diagnosed as coronary insufficiency.

Rhythm disturbances were infrequent during isometric exercise in our series as in those of others,[10,11,16] in contrast to the findings of Atkins et al.[17] We have no explanation for this inconsistency. Nevertheless, we recommend a conservative approach in evaluating the safety of isometric exercise in patients with coronary artery disease.

Myocardial function during isometric vs. dynamic exercise: Isometric exercise tests are relatively innocuous. This is surprising since they produce significant arterial hypertension; the increment in aortic pressure found in our patients was similar to that found by Lind et al.[1] in normal subjects. Tension-time index and pressure-heart rate product have been proposed as indexes of myocardial oxygen consumption. But we have found that these values are lower during maximal dynamic exercise producing angina than at the end of isometric exercise, although the latter exceptionally produces signs of coronary insufficiency when performed alone and frequently (about 50 percent of patients) when performed in combination with submaximal dynamic exercise.

It is possible that these indexes are not fully representative of myocardial oxygen consumption, especially during exercise.[18] Other determinants of cardiac metabolism—heart rate, cardiac output, ventricular wall tension and contractility—may play a role.[19] Moreover, myocardial energy requirements being equal, adaptation of coronary circulation could be different during isometric and dynamic exercise, resulting in different electrocardiographic responses. Finally, the duration as well as the intensity of the myocardial stress should be considered. The duration of dynamic exercise, presumably resulting in accumulation of an oxygen debt, is to a great extent responsible for both angina and S–T segment changes. Near maximal work loads are carried out for a longer period with dynamic than with isometric exercise. Since no steady hemodynamic state is reached during isometric exercise, the heavy myocardial stress caused by this test is of very short duration compared to that seen in dynamic effort. This is certainly why this method of stress rarely elicits evidence of latent coronary insufficiency.

Clinical implications: Our study demonstrates that isometric exercise testing is not suitable for diagnosing coronary insufficiency. The prevalence of S–T segment changes or angina is small during isolated isometric exercise compared to maximal dynamic exercise, but is somewhat greater during combined submaximal dynamic and isometric exercise.

These results are surprising since values for tension-time index and pressure-heart rate product were higher at the end of isometric exercise, isolated or coupled with submaximal dynamic exercise, compared to values found at the end of maximal dynamic exercise. Thus, individually considered, these indexes do not explain the relatively good tolerance for isometric testing manifested by our patients with coronary disease. The duration of maximal stress to which the heart is exposed may be a factor since this period is much shorter in isometric exercise than in dynamic effort.

Comparison of the Two-Step and Maximal Exercise Tests in Patients with Coronary Artery Disease

PAUL SCHWEITZER, MD
V. MICHAEL JELINEK, MD, FRACP
MICHAEL V. HERMAN, MD, FACC
RICHARD GORLIN, MD, FACC

Boston, Massachusetts

This study has investigated the claim that the electrocardiographic response to the maximal exercise test provides a more accurate method of assessing the presence and severity of coronary artery disease than the electrocardiographic response to the two-step test. One hundred and one men with a chest pain syndrome underwent the two-step test, maximal exercise test and coronary angiography during the same admission. There was a preponderance of men who performed the maximal exercise test as a result of a negative two-step test. A positive two-step test was defined as horizontal or downsloping S–T segment depression of 0.5 mm or more, whereas a positive maximal exercise test was defined as similar S–T segment depression of 1.0 mm or more. Of the 17 men with no or insignificant coronary artery disease, 5 had a positive two-step test and 6 a positive maximal exercise test. Of the 84 men with coronary artery disease, 33 had a positive two-step test and 38 a positive maximal exercise test. Thus, the specificity of the two-step test for coronary artery disease was 87 percent and that of the maximal exercise test was 86 percent; the respective sensitivity rates were 39 and 45 percent. The percentage of positive results of both exercise tests increased similarly with the severity of coronary artery disease.

Nine patients, eight of whom had coronary artery disease, had a positive maximal exercise test but a negative two-step test; in these patients the maximal heart rate was significantly higher during the maximal exercise test than during the two-step test. Five patients, all with coronary artery disease, had a positive two-step test but a negative maximal exercise test. One patient manifested 0.5 mm S–T segment depression in both tests and was thus judged to have a positive two-step test and a negative maximal exercise test. In another patient results were positive in lead V_4 of the two-step test, a lead not recorded in the maximal exercise test. The other three patients had had positive results in a second maximal exercise test recorded in the supine position, thus demonstrating that in certain cases the effects of augmented venous return in the supine position may be as important a factor in eliciting ischemia as the achieved heart rate.

There has been a recent tendency to replace the two-step exercise test with submaximal[1–3] or maximal[3–5] exercise testing for evaluation of patients with chest pain. It has been claimed not only that the work load of the two-step test is relatively light, and therefore insufficient to detect lesser degrees of coronary artery disease, but also that the maximal exercise test allows for better quantification and control of stress applied to the patient. For a definitive answer on the relative merits of the two-step and maximal exercise tests in detection of coronary artery disease, both tests must be performed in the same group of patients whose coronary anatomy has been defined. In this study we carried out such an investigation, and the results form the basis of our report.

TABLE I

Sensitivity and Specificity of Exercise Criteria

Results of Exercise Test	Results of Coronary Angiography: CAD	NCAD
Positive	A	B
Negative	C	D

Sensitivity of exercise criterion = A/(A + C) expressed as percent.

Specificity of exercise criterion = A/(A + B) expressed as percent.

Thus, false positive results = 100 — specificity; false negative results = 100 — sensitivity.

CAD = coronary artery disease; NCAD = no or insignificant coronary artery disease.

TABLE II

Comparison of the Two-Step and Maximal Exercise Tests

Patients (no.)	S–T Segment Depression: Two-Step Test: None no.	%	0.5–1 mm no.	%	>1.0 mm no.	%	Maximal Exercise Test: None no.	%	≥1.0 mm no.	%
NCAD(17)	12	70.5	4	23.5	1	6.0	11	64.8	6	35.2
CAD(84)	51	60.7	11	13.1	22	26.2	46	55.0	38	45.0

CAD = patients with coronary artery disease; NCAD = patients with insignificant coronary artery disease or no disease; no. = number of patients.

TABLE III

Sensitivity and Specificity of the Two-Step and Maximal Exercise Tests

	Sensitivity (%)	Specificity (%)
Two-step test		
0.5 mm S–T depression	39	87
1.0 mm S–T depression	26	97
Maximal exercise test (1.0 mm S–T depression)	45	86

Materials and Methods

The study group comprised 101 men with a chest pain syndrome. Their average age was 47 years. All patients underwent the two-step test, maximal exercise test and coronary angiography during the same admission. There was a preponderance of men with negative two-step tests who had subsequent maximal exercise tests. The two exercise tests were usually performed on the same day with the two-step test preceding the maximal exercise test by 1 hour. Standard 12 lead electrocardiograms were recorded with patients in the supine position before, immediately after and during the 3rd, 5th and 8th minutes after the two-step test.[6] The maximal exercise test was performed on a bicycle ergometer. The initial work load was 300 kilopond-meters (kpm) and this load was increased by 150 kpm every 3 minutes until the patient manifested chest pain, fatigue or marked ventricular arrhythmia. Seven lead electrocardiograms were recorded with the patient sitting on the bicycle; the six limb leads and lead V_5 were recorded at the same time intervals as those used during the two-step test. In addition, lead V_5 was monitored throughout exercise and recorded for 10 seconds at the end of every minute of exercise.

A positive two-step test was defined as horizontal or downsloping S–T segment depression of 0.5 mm or more.[7] A positive maximal exercise test was defined as horizontal or downsloping S–T segment depression of 1.0 mm or more on the basis of previously published criteria for such tests.[1–3] The latter criterion has been advocated as providing the optimal levels of specificity and sensitivity for S–T segment change during a maximal exercise test.[4]

Coronary arteriography was usually performed on the day after exercise testing. The technique of angiography used in this laboratory has been described previously.[8] Obstructive lesions were defined as those occluding 75 percent or more of the vessel lumen, as estimated by the combined dimensional analysis of the two oblique views. Patients with obstructive lesions of one, two or three major coronary arterial systems comprised the group with coronary artery disease. The group with normal coronary arteriograms included some patients with minor luminal irregularities as well as those without evidence of atherosclerosis.

Sensitivity and specificity were analyzed as shown in Table I.

Results

There were 84 men with coronary artery disease and 17 men with normal coronary arteries. The patients with coronary artery disease were further classified into those with one, two or three vessel disease—28, 26 and 30 patients, respectively.

Detection of coronary artery disease and exercise tests (Tables II and III): The 17 patients with normal coronary arteries had five positive two-step tests and six positive maximal exercise tests. The 84 patients with coronary artery disease had 33 positive two-step tests and 38 positive maximal exercise tests. When 1 rather than 0.5 mm S–T segment depression was taken as a criterion for a positive two-step test, only 22 patients with coronary artery disease and 1 with normal coronary arteries exhibited such a response. Thus, the sensitivity in detection of coronary artery disease of a positive two-step test based on a criterion of 0.5 mm S–T segment depression was 39 percent compared with 45 percent for a positive maximal exercise test. The specificity of the two-step test was 87 percent and that of the maximal exercise test 86 percent. If a 1 mm criterion was taken for a positive two-step test, the specificity was 97 percent but the sensitivity decreased to 26 percent.

Severity of coronary artery disease and exercise tests (Tables IV and V): The percentage of positive tests increased with the severity of coronary artery disease. However, the sensitivity levels of the two-step and maximal exercise tests were similar for all degrees of coronary artery disease and demonstrated no statistical difference.

TABLE IV

Comparison of the Two-Step and Maximal Exercise Tests in Patients with Different Degrees of Coronary Artery Disease

Patients (no.)	S–T Segment Depression									
	Two Step Test						Maximal Exercise Test			
	None		0.5–1.0 mm		>1.0 mm		None		>1.0 mm	
	no.	%	no.	%	no.	%	no.	%	no.	%
1VD (28)	22	78.6	4	14.3	2	7.1	22	78.6	6	21.4
2VD (26)	15	57.7	4	15.4	7	26.9	11	42.3	15	57.7
3VD (30)	14	46.7	3	10.0	13	43.3	13	43.3	17	56.7

1VD = obstructive disease of one major coronary arterial system; 2VD = obstructive disease of two major coronary arterial systems; 3VD = obstructive disease of three major coronary arterial systems; no. = number of patients.

Variance in results between exercise tests (Tables VI and VII): Five patients had a positive two-step test and a negative maximal exercise test. All patients in this category had coronary artery disease. In three patients of this group, the achieved heart rate was higher during the maximal exercise test than during the two-step test, and in two patients the same heart rate was achieved during both tests.

To explain the results in these five patients, individual case analysis was performed. The first patient had 0.5 mm S–T depression on both tests and was therefore considered to have a negative maximal exercise test. Another patient manifested S–T depression only in lead V_4 after the two-step test, and this lead was not recorded during or after the maximal exercise test. Neither of these explanations applied to the other three patients who therefore underwent a second maximal exercise test. The electrocardiogram after the second maximal exercise test was recorded with the patient lying supine instead of sitting on the bicycle. In all three cases, the second maximal exercise test was positive.

Nine patients, one with normal coronary arteries, had a positive maximal exercise test and a negative two-step test. In these patients the maximal mean heart rates in the two-step and maximal exercise tests were 88 and 134 beats/min, respectively ($P < 0.05$).

Discussion

The purpose of our study was to compare the diagnostic value of the two-step and the maximal exercise tests in symptomatic patients. Our results show that the sensivitity and specificity of the two tests are very similar when the S–T segment criteria defined earlier are used. In addition, we have confirmed the results of reports[4,8,9] showing that if 1.0 mm S–T segment is used as a positive end point for the two-step test, the sensitivity markedly decreases but the specificity becomes greater.

The sensitivity ranges between 35 and 84 percent[4,8–10] depending in part on the criteria used for heart rate and S–T segment depression. The lower levels of sensitivity reported in our study may repre-

TABLE VII

Achieved Heart Rate in Nine Patients with a Positive Maximal Exercise Test and a Negative Two-Step Test

Test	Heart Rate (beats/min)
Two-step test	88 (68–100)
Maximal exercise test	134 (88–100)
P value	<0.05

sent inadvertent error in sampling of patient population, and particularly the low level of heart rate achieved in some subjects (Tables VI and VII). The prevalence of false positive results is similar to that reported by Kemp et al.[11] in patients with angina pectoris and normal coronary arteries.

One of the main objections to the two-step test is that it cannot detect mild or moderate degrees of coronary artery disease. From the analysis of our results, it is evident that neither the two-step test nor the maximal exercise test is of great help in the diagnosis of coronary artery disease in patients with single vessel disease, but both tests are more sensitive in multivessel disease.

An important finding is that in individual patients the results of the two-step and maximal exercise tests may differ. It is reasonable to assume that the occurrence of a positive maximal exercise test after a negative two-step test in nine cases was a result of the higher heart rate achieved during the maximal exercise test and the recording of electrocardiograms during and after exercise. The positive two-step test but negative maximal exercise test of five patients is more difficult to explain. In one case, 0.5 mm S–T depression occurred with both tests, and the results were interpreted as a positive two-step test but a negative maximal exercise test. In another case, the recording of only seven leads during the maximal exercise test prevented detection of the ischemic response observed in lead V_4 of the two-step test lead system. In the remaining three cases, it could be shown that the results were influenced by the recording of the electrocardiogram with the patient in the supine position after the two-step test but in the upright position after the maximal exercise test. When the initial maximal exercise test was negative after a two-step test had been positive, a second maximal exercise test was performed in which the electrocardiogram was recorded after exercise with the patient supine. Each of the three patients had an ischemic response not seen previously. This finding suggests that, in certain subjects, the effects of augmented venous return in the supine position[12–15] in increasing cardiac mechanical activity through the Starling effect may be as important a factor in eliciting ischemia as achieved heart rate.[16]

Our results have the following implications for practice: (1) In the majority of cases of chest pain, the sensitivity and specificity of the two-step and maximal exercise tests for coronary artery disease are similar. (2) Patients with an inadequate increase of heart rate after the two-step test should perform a maximal exercise test or, in an alternative practical approach for use in the physician's office, continue the two-step test until higher heart rates are achieved (110 to 120 beats/min). (3) The electrocardiogram should be recorded with the patient in the supine position after exercise if a maximal exercise test is used.

Arm-Crank Ergometry: A New Method for the Evaluation of Coronary Artery Disease

DAVID J. SHAW, MD
MICHAEL H. CRAWFORD, MD
JOEL S. KARLINER, MD, FACC
GEORGE DiDONNA, MD
RICHARD M. CARLETON, MD, FACC
JOHN ROSS, Jr., MD, FACC
ROBERT A. O'ROURKE, MD, FACC*

La Jolla, California

We have developed an electrocardiographic stress test to evaluate coronary heart disease using an arm-crank device (modified bicycle ergometer) in patients unable to perform leg exercise. With an initial work load of 200 kg-m/min at 40 revolutions/min for 3 minutes, followed by 100 kg-m/min increments every 3 minutes to a maximum of 700 kg-m/min at the same speed, a linear relation between the increase in heart rate and work load was observed. Twenty-one patients underwent both conventional treadmill exercise (modified Bruce protocol) and arm-crank exercise on separate days. Peak heart rate was slightly slower with arm-crank exercise (81 ± 4 [standard error] vs. 85 ± 3 percent of maximal predicted heart rate for age, $P < 0.02$) but peak systolic blood pressure and heart rate-systolic blood pressure product (double product) did not differ significantly (157 ± 7 vs. 154 ± 6 mm Hg, $P > 0.5$) and (22.0 ± 1.2 vs. 22.5 ± 1.2 × 10^3, $P > 0.1$). Ten patients with documented coronary artery disease, including 7 with angina pectoris, had an ischemic S–T segment response (0.08 second depression greater than 1 mm) by both methods and 10 patients (7 with previous myocardial infarction and 3 with normal coronary arteriograms) had negative results by both techniques. One patient with normal coronary arteriograms had a negative arm-crank test and a positive treadmill test. In 26 patients unable to perform leg exercise the mean peak heart rate, systolic blood pressure and double product with arm-crank exercise were not significantly different ($P > 0.05$) from those achieved by the ambulatory patients (73.2 ± 1.9 vs. 81.0 ± 4.0 percent, 167 ± 8 vs. 157 ± 7 mm Hg and 22.4 ± 1.2 vs. 22.0 ± 1.4 × 10^3, respectively). Six of 26 patients unable to perform leg exercise had a positive arm-crank test. Four of these six patients had angina pectoris and three had a previous myocardial infarction. We conclude that arm-crank exercise is comparable to treadmill exercise and is a reliable alternative method for the evaluation of suspected coronary artery disease in patients unable to perform leg exercise.

Exercise electrocardiography is of considerable value in the diagnosis and functional evaluation of patients with known or suspected ischemic heart disease.[1,2] However, currently available techniques, including the two-step, treadmill, escalator and bicycle ergometer tests, all require leg exercise. Thus, these methods are not applicable to a large population of patients at risk from ischemic heart disease who also have peripheral vascular disease, large joint arthritis, amputations or neuromuscular problems involving the lower limbs. A number of these patients will become potential candidates for elective surgical procedures of various types. The recognition of significant ischemic heart disease in these patients either may serve as a relative contraindication to certain surgical procedures or may aid perioperative management. In addition, in some patients angina pectoris is precipitated primarily by arm exertion. Accordingly, we have devised

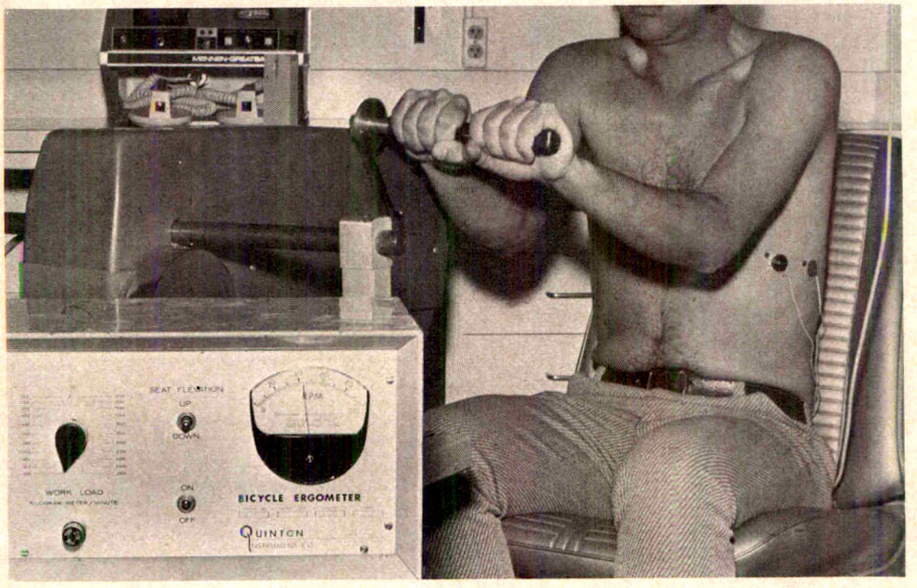

FIGURE 1. The arm-crank device in operation. The fulcrum is at shoulder level of the seated subject who cranks clockwise against a variable torque by turning a 10 inch long steel shaft fitted with two molded plastic handgrips. An electrocardiographic machine is available for constant monitoring.

a graded arm-crank exercise test that permits clinical evaluation of patients unable to perform leg exercise.

The purposes of this study were (1) to devise a program of graded arm-crank exercise combined with electrocardiographic monitoring in a fashion analogous to that of standard tests utilizing leg exercise, (2) to compare the results of such arm exercise with the results of conventional treadmill exercise in patients capable of performing the latter, and (3) to determine the applicability of an arm exercise test for evaluating patients unable to perform leg exercise.

Methods

Forty-seven patients were studied by arm-crank ergometry. There were 7 women and 40 men ranging in age from 41 to 74 years (mean age 57 years). Twenty-one patients were able to perform both arm-crank and treadmill exercise, and 26 patients were able to perform arm-crank exercise only. The 21 patients able to perform both tests included 17 patients with a documented myocardial infarction and 4 patients with atypical chest pain who had normal coronary arteriograms. The diagnosis of myocardial infarction was made on the basis of (1) a history of typical prolonged chest pain, (2) electrocardiographic changes indicative of acute myocardial injury with subsequent evolution of a typical infarction pattern with diagnostic Q waves, and (3) characteristic elevation of serum enzyme levels (creatine phosphokinase [CPK], glutamic oxaloacetic transaminase [SGOT] or lactic dehydrogenase [LDH]). Three of the 17 patients with a prior myocardial infarction had coronary arteriograms that were diagnostic of significant obstructive disease (greater than 50 percent stenosis of one or more major coronary arteries). The 26 patients who could perform only arm-crank exercise included 14 patients with arteriosclerotic peripheral vascular disease, 4 patients with arthritis affecting the legs, 2 patients with amputated legs, 4 patients with a hip prosthesis and 2 patients with neurologic disease. Six of these patients had a documented previous myocardial infarction, and one additional patient had angiographically documented coronary artery disease.

All patients had a complete history and physical examination. A standard 12 lead electrocardiogram was obtained immediately before each exercise test. No patient was tested who had a myocardial infarction within 3 months, an acute febrile illness or unstable angina pectoris. No patient had received a digitalis preparation within 10 days before the study and, in three patients receiving propranolol, this drug was discontinued at least 48 hours before the study.[3] Subjects who were able to perform treadmill exercise performed arm-crank and treadmill tests on separate days, and the order of the tests was randomly alternated. All patients were studied in the postabsorptive state.

The arm-crank device (Fig. 1) consisted of a modified Quinton bicycle ergometer mounted so that the fulcrum of the crank was at shoulder level when the subject was seated. A single pedal on the 6 1/2 inch long radial arm was replaced by a 10 inch long steel shaft fitted with two molded plastic handgrips. The ergometer was so positioned that the subject cranked clockwise with both arms against a variable torque from a seated position. The seat to arm-crank distance was adjusted for each patient to permit coordinated trunk movement with arm-cranking. The graded exercise program, selected empirically after trials in volunteer subjects, consisted of an initial external work load of 200 kg-m/min sustained for 3 minutes, followed by 100 kg-m/min increments every 3 minutes. Cranking speed was maintained at 40 revolutions/min. The highest work load achieved was 700 kg-m/min. The electrocardiogram was monitored during and after the test utilizing fluid-column electrodes for modified leads CR_5 and CR_6. The right lead was placed just medial to the upper scapula posteriorly. The ground electrode was placed just below the right costal margin, and the CR_5 and CR_6 electrodes were located in their usual precordial positions. Leads CR_5 and CR_6 were recorded at 1 minute intervals during exercise and also after exercise until the heart rate had returned to 100 beats/min or less. The systemic arterial pressure was measured by cuff sphygmomanometer immediately before and within 5 seconds of the conclusion of exercise. Treadmill

exercise testing was performed utilizing a modified Bruce protocol.[1] The lead system and recording techniques were identical to those used in the arm-crank test.

Electrocardiographic criteria used for scoring each test as positive or negative were those proposed by Sheffield and co-workers.[4] An ischemic response was defined as the conversion of isoelectric to depressed S–T segments during or after exercise. Depression of the S–T segments was considered to be significant when there was at least 0.1 mv of J point depression and the slope of the first 80 msec of the S–T segment toward the base line was less than 1 mv/sec.[4] Either test was discontinued by the monitoring physician if ischemic changes on the electrocardiogram occurred, if 90 percent of the maximal predicted heart rate was achieved or if chest pain, dyspnea or fatigue precluded further exercise. Before treadmill exercise, control tracings were obtained in all patients in both the seated and standing positions as well as during hyperventilation while standing. Before arm-crank exercise, tracings were obtained with patients in the seated position at rest and during hyperventilation. Data were analyzed utilizing standard statistical methods.[5]

Results

Arm-Crank Ergometry

No patient experienced any difficulty initiating arm exercise with this device. The duration of exercise ranged from 1.67 to 20 minutes and averaged 8.2 ± 0.7 (standard error) minutes. Fourteen of the 47 patients were able to exercise 9 minutes or longer (stage III or better). In these 14 patients, there was a linear relation between heart rate and work load (Fig. 2). No significant training effect was observed in six subjects who performed two arm-crank tests several days apart.

The need to place the lead system in close proximity to exercising muscle groups caused some base-line movement artifact that rarely precluded interpretation during exercise and could often be reduced by fastidious electrode preparation. No recording problems were encountered after exercise was stopped. The only complication encountered with arm-crank exercise occurred in one patient who experienced painful forearm muscle cramps.

Comparison with Treadmill Exercise

Electrocardiographic response: Of the 21 patients who performed both tests, 10 demonstrated ischemic S–T segment responses to both arm-crank and treadmill exercise; 10 additional patients had a negative response to both tests. There was only one discordant S–T segment response. This occurred in a 45 year old man with a normal left ventriculogram and normal coronary arteriograms who had a positive treadmill test at a maximal heart rate-systolic blood pressure product (double product) of 17.2×10^3 and a negative arm-crank test at a double product of 19.2×10^3.

Hemodynamic response: The duration of exercise was slightly longer with the arm-crank test (8.0 ± 0.7 vs. 6.6 ± 0.6 minutes) but the difference was not significant ($P > 0.1$, paired t test). The maximal heart rate (expressed as percent of maximal predicted heart rate for age) was slightly slower with arm-crank exercise than with treadmill exercise (81 ± 4 vs. 85 ± 3 percent), but this difference was of borderline significance ($P < 0.02$). Peak systolic blood pressure and double product in the two tests did not differ significantly (157 ± 7 vs. 154 ± 6 mm Hg, $P > 0.5$) and (22.0 ± 1.2 vs. $22.5 \pm 1.2 \times 10^3$, $P > 0.1$). Figure 3A displays the paired cardiovascular responses in the patients with positive exercise tests and Figure 3B shows the same variables in patients with negative responses to exercise. As with findings for the total group, there was no significant difference between the paired cardiovascular responses of patients with either positive or negative tests.

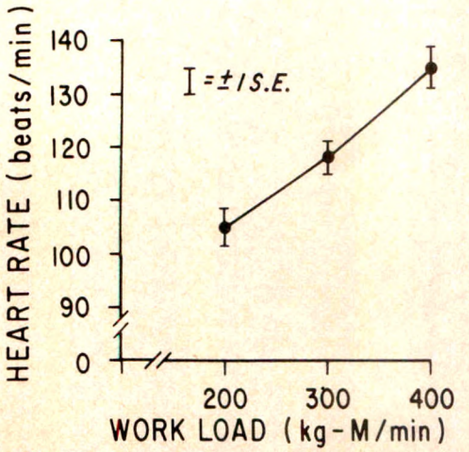

FIGURE 2. The linear relation between absolute heart rate and work load in 14 patients undergoing arm-crank exercise. S.E. = standard error.

Arm-Crank Ergometry in Patients Unable to Perform Leg Exercise

Arm-crank exercise was used to evaluate 26 patients unable to perform leg exercise. These patients achieved a lower heart rate and a higher peak systolic blood pressure than the ambulatory patients, but the differences were not significant (73.2 ± 1.9 vs. 81.0 ± 4.0 percent, $P > 0.05$ and 167 ± 8 vs. 157 ± 7 mm Hg, $P > 0.1$). The double products were virtually identical when the responses of nonambulatory and ambulatory patients were compared (22.4 ± 1.2 vs. $22.0 \pm 1.4 \times 10^3$, $P > 0.5$).

Eight of the 26 nonambulatory patients had typical symptoms of angina pectoris and 4 had a positive arm-crank test; 3 of these 4 had a prior myocardial infarction. Of the four patients with angina who had negative tests, one had coronary artery disease documented by angiography and another had a previous myocardial infarction. However, the double products in the patients with negative tests ranged from 12.5 to 14.0×10^3 in contrast to a range of 21.7 to 26.1×10^3 in the group with positive tests.

The remaining 18 patients underwent arm-crank exercise for various reasons including atypical chest pain and arrhythmia evaluation. Two of these pa-

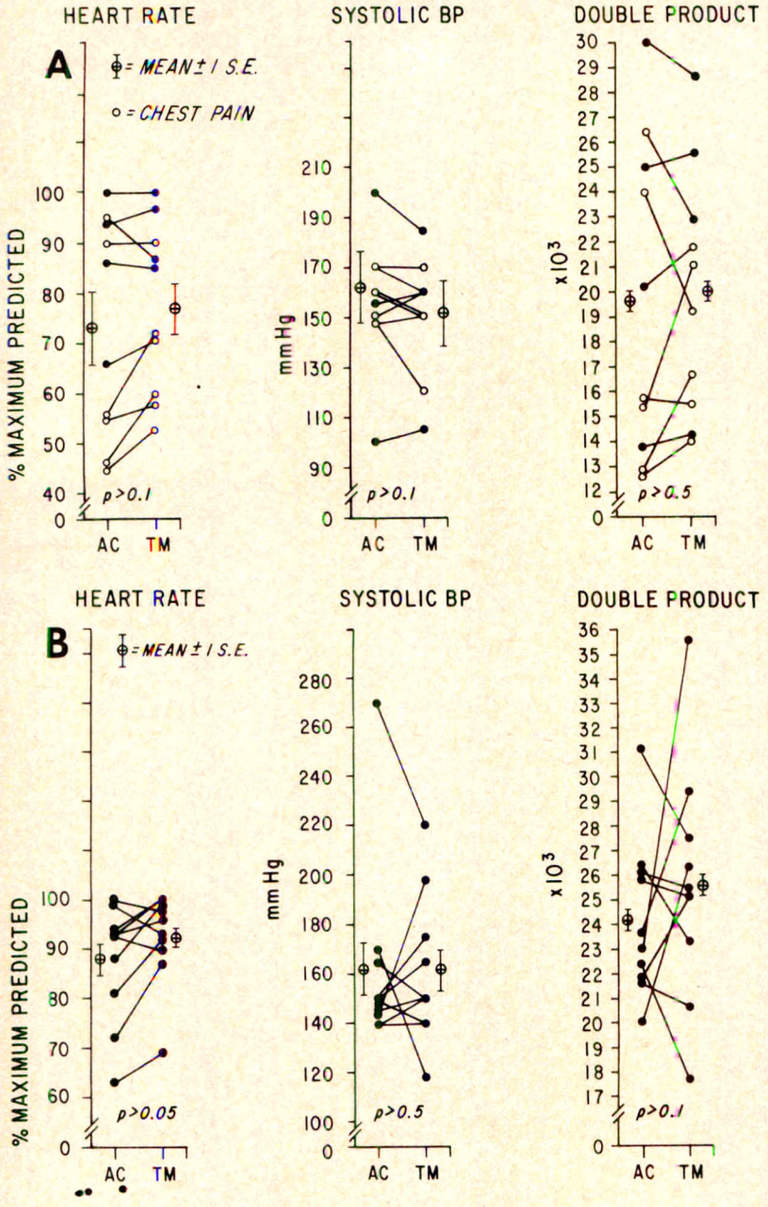

FIGURE 3. Data on heart rate (as percent of the maximal predicted heart rate for age), systolic arterial pressure and double product (absolute heart rate × systolic arterial pressure) in the 10 patients who had positive responses to both tests **(A)** and the 10 patients who had negative responses to both tests **(B).** The data show no significant differences between values obtained during the two tests. AC = arm-crank; BP = blood pressure; S.E. = standard error; TM = treadmill.

tients had positive tests but coronary arteriograms were not obtained because the patients were not considered candidates for coronary arterial surgery. Sixteen of these 18 patients had negative arm-crank studies, including two patients with prior myocardial infarction who had no history of angina pectoris. The range of double products in this group was 14.0 to 32.6×10^3 and the mean was $22.4 \pm 1.8 \times 10^3$.

Discussion

Arm-crank exercise has been extensively investigated in normal subjects[6–8] and has been reported to produce higher heart rates and blood pressures than equivalent work loads with leg exercise in such persons[9,10] and in patients with suspected coronary artery disease.[11] These findings have been used to explain the occurrence of angina pectoris exclusively with arm exercise in certain patients. In our patients we found no significant difference between arm and leg exercise with respect to heart rate and blood pressure at the end of exercise. Previous investigations have used a double-handled cranking device that required the arms to move in opposite directions. With this type of device, considerable static work must be performed by the trunk muscles. By contrast, in our technique the two arms and trunk move together, a method that is more efficient.[12] Thus, the dynamic use of arm and back muscles in our test is probably more comparable to treadmill exercise.[13]

In subjects able to perform both tests there were no statistically significant differences between the paired cardiovascular responses to the arm-crank and treadmill tests. Three of the 10 patients who had negative responses to both studies did not achieve 85

percent of their maximal predicted heart rate with arm-crank exercise. Achievement of this rate during treadmill exercise has been associated with a high degree of sensitivity in relation to coronary arterial obstruction.[3] However, two of these patients achieved higher double products with the arm-crank test. Since the double product is a reliable estimate of myocardial oxygen demand,[14,15] sensitivity of the arm-crank test was probably equal to that of the treadmill test in these two patients. When S–T segment changes were compared, the only difference between the two tests in our patients was that one patient with a negative arm-crank study had a false positive treadmill test. Thus, arm-crank exercise produced heart rate and blood pressure responses similar to those of treadmill exercise in our patients, and was equally as sensitive in detecting coronary artery disease.

We have demonstrated that arm-crank exercise can be accomplished by patients unable to perform leg exercise and that coronary artery disease can be detected by this method in such patients. Many of the nonambulatory patients with negative arm-crank studies did not reach 85 percent of their maximal predicted heart rate. The mean percent of the maximal predicted heart rate in these 20 patients was 73 percent. Nevertheless, because of higher blood pressures the mean double product achieved by these nonambulatory patients was not significantly different from that achieved by the ambulatory patients with negative arm-crank studies (22.4 ± 1.8 vs. 24.2 ± 1.0, $P > 0.1$). Therefore, the sensitivity of the arm-crank test in nonambulatory patients appears to be comparable to that observed in the ambulatory patients who had similar responses to arm-crank and treadmill exercise.

We have found the arm-crank test useful for evaluating chest pain and palpitation in patients unable to perform conventional leg exercise. Many of these patients are candidates for vascular and other types of surgery and the information obtained is helpful in their perioperative management. We have also used arm-crank ergometry to help elucidate chest pain induced exclusively by arm exercise in ambulatory patients. Presumably, this type of exercise would also be useful for assessing responses to drug therapy and physical rehabilitation programs.

In conclusion, we have demonstrated that a graded arm-crank exercise test is comparable to graded treadmill exercise in producing changes in heart rate and blood pressure sufficient to induce ischemic electrocardiographic changes in patients with coronary artery disease. In addition, we have shown the feasibility of utilizing this test to assess patients who are unable to perform leg exercise. Therefore, arm-crank ergometry is an excellent alternative to conventional treadmill exercise for evaluating suspected coronary artery disease in nonambulatory patients.

Effects of Perhexiline on Symptomatic and Hemodynamic Responses to Exercise in Patients with Angina Pectoris

CARL J. PEPINE, MD
STEVEN J. SCHANG, MD
CARL R. BEMILLER, MD, FACC

Philadelphia, Pennsylvania

The effects of perhexiline on symptomatic and hemodynamic responses to exercise stress were evaluated in 16 patients with coronary artery disease and angina pectoris. Exercise-induced angina was prevented (12 of 16) or delayed during perhexiline treatment and exercise heart rate decreased (117.4 ± 6.1 [standard error of the mean] to 105.3 ± 3.6 beats/min, $P < 0.05$). Ischemia-related indexes of left ventricular dysfunction were attenuated (stroke work index 70.9 ± 5.7 to 86.4 ± 5.3 g-m/beat per m^2 and filling pressure 26.4 ± 3.0 to 17.7 ± 2.5 mm Hg, $P < 0.01$) without evidence for depression of other indexes of ventricular function. Additionally, the exercise diastolic pressure-time index increased 36.5 ($P < 0.01$) and the diastolic pressure-time/tension-time ratio increased 38 percent ($P < 0.05$) with perhexiline in the patients who were free of angina. During increased exercise stress six patients achieved higher tension-time indexes before being limited by fatigue or dyspnea. The observed beneficial effects appear to be partly a result of reduced myocardial oxygen needs and improved oxygen supply.

Infusion of perhexiline (2-[2,2-dicyclohexylethyl] piperidine) produces coronary vasodilation and reduces heart rate in animals.[1,2] In normal subjects, this compound decreases the tachycardia induced by exercise.[3] These properties suggest that perhexiline, which is chemically unrelated to currently available antianginal agents, might be useful in patients with myocardial ischemia. Preliminary trials in patients with angina pectoris have generally shown improved exercise tolerance and a reduction in frequency and severity of anginal episodes.[4–6] Recently, data have been presented to suggest that perhexiline also has potent antiarrhythmic[7] and bronchodilator[8] actions that could be beneficial in patients with complicated angina. Furthermore, when the agent is administered orally, the duration of these effects has been long, apparently because perhexiline and its active derivatives are retained with lengthy biologic half-lives.[9] However, to date the potential clinical usefulness of perhexiline remains controversial,[10] and its hemodynamic effects have not been thoroughly examined.

An evaluation of the hemodynamic effects of perhexiline in patients with coronary artery disease complicated by angina pectoris constitutes the subject of this investigation. Because of the subjective nature of antianginal responses alone, emphasis is placed on the influence of perhexiline on ischemic ventricular performance during exercise. These actions are reviewed in terms of the effects observed with currently used antianginal agents.

Materials and Methods

Sixteen patients aged 43 to 67 years (mean 52 years) with stable angina pectoris and angiographically significant (greater than 75 percent obstruction) coronary artery disease comprised the study group (Table I). All pa-

DM = diabetes mellitus; ECG = electrocardiogram; LAD = significant narrowing of left anterior descending coronary artery; LC_x = significant narrowing of left circumflex coronary artery; − = less than 1 mm ischemic S-T segment depression; MI = myocardial infarction; NYHA Class = New York Heart Association functional classification; + = S–T segment depression of 1 mm or more; RBBB = right bundle branch block; SVBG = saphenous vein bypass graft.

tients were in functional class II or III of the New York Heart Association classification and had no evidence for congestive heart failure or other forms of heart disease. Administration of other antianginal agents was stopped 1 week before the study, but nitroglycerin was permitted until the day of the study. Before the study, all subjects gave informed consent to participation in an antianginal drug investigation that included the procedures outlined herein. All catheterizations were performed without premedication with the patients in a fasting state, and all data reported were obtained before administration of angiographic contrast agents.

Procedures: A no. 7 Cournand type catheter was positioned in the main pulmonary artery by way of an antecubital vein. Systemic arterial pressure was measured with use of an 18G Teflon® catheter inserted percutaneously into a brachial artery and a Statham P23Db transducer. Heart rate and S–T segment depression were measured from electrocardiographic lead V_5. Cardiac output and pressure recordings were obtained according to methods described in detail previously.[11] The catheter was advanced to the pulmonary capillary wedge position where left ventricular filling pressure, as reflected in the mean pulmonary capillary wedge pressure, was recorded from a Statham P23Db transducer. Diastolic pressure-time index was calculated according to the method of Buckberg et al.[12] from the area under the diastolic systemic arterial pressure curve by subtracting from this value the mean pulmonary capillary

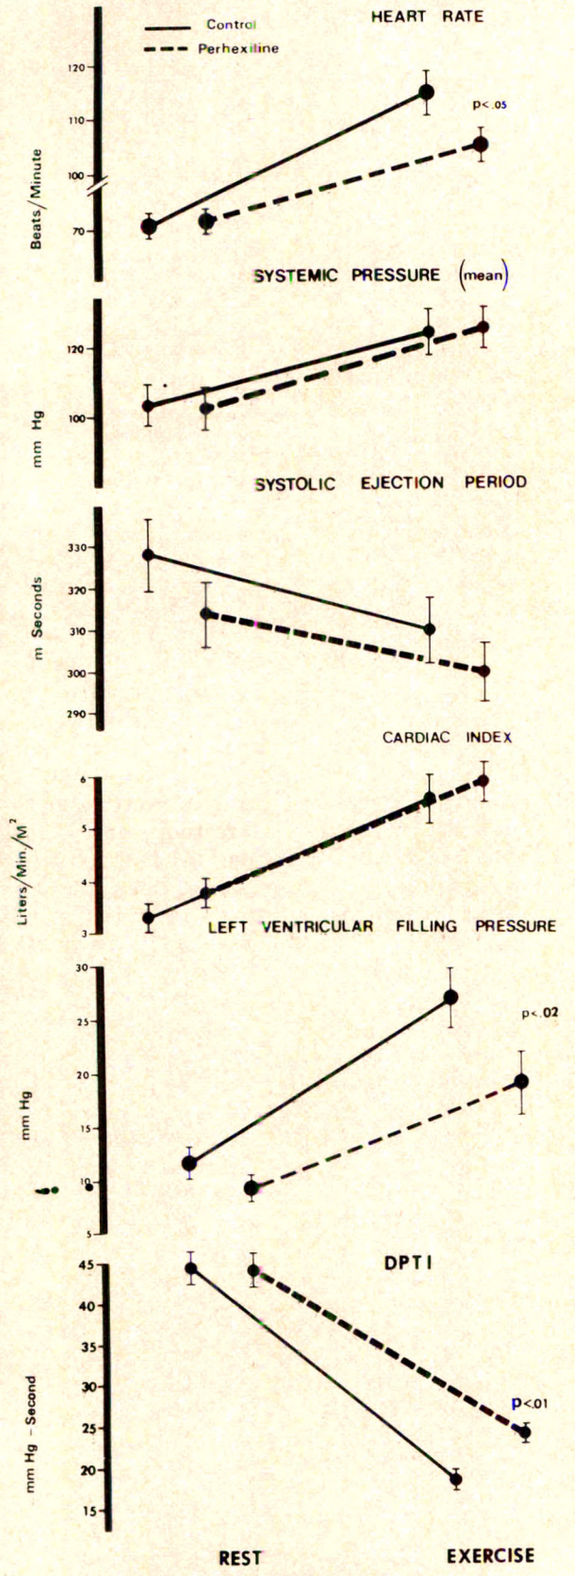

FIGURE 1. Summary of measurements at rest and during exercise before **(solid line)** and after **(dashed line)** perhexiline. Values represent means ± standard error of the means. DPTI = diastolic pressure-time index.

wedge pressure. These hemodynamic measurements were made at rest. Each patient then performed supine leg exercise on a bicycle ergometer (Collins) at a constant, individualized work load previously determined to evoke angina pectoris consistently after 3 to 5 minutes. The details of this exercise protocol and its ability to assess other antianginal interventions have been previously reported from our laboratory.[13,14] The pressure and cardiac output measurements were repeated during exercise-induced angina pectoris. All data were recorded on a multichannel photographic recorder at a speed of 25 mm/sec. Recording speeds of 200 mm/sec were used for the systolic ejection period and diastolic pressure-time index measurements and 10 mm/sec for cardiac output determinations.

After the initial study, the patients began taking perhexiline (200 mg orally, twice daily). After at least 10 days of therapy, they were restudied in an identical manner 4 hours after their morning dose. The exercise work load and duration were identical to those of the control test before administration of perhexiline, and data were collected at the same time during exercise. Patients not experiencing angina then continued exercise to the point of fatigue, or a maximum of 6 minutes. Results were analyzed statistically by the *t* test for paired data.

Follow-up studies: After completion of the restudy the patients were discharged from the hospital and followed up at biweekly intervals. During this period they took either perhexiline or placebo in a double-blind crossover study. All patients kept daily diaries and returned for reevaluation of exercise tolerance at monthly intervals, using the previously described protocol.

The following formulas were used: systolic ejection period (SEP) in seconds; cardiac index (CI) in liters/min per m^2 = cardiac output/body surface area; left ventricular stroke work index in g-m/beat per m^2 = CI/HR × (mean systolic pressure − mean pulmonary capillary wedge pressure) × 1.36/100; left ventricular work index in kg-m/min per m^2 = CI × (mean systolic pressure − mean pulmonary capillary wedge pressure) × 1.36/100; tension-time index (TTI) in mm Hg-sec/min = (mean systolic pressure) (HR)(SEP): diastolic pressure time index (DPTI) in mm Hg-sec; DPTI/TTI = (DPTI)(HR)/TTI: mean systolic ejection rate, in ml/sec per m^2 = CI/HR/SEP; systemic vascular resistance = mean systolic pressure/cardiac output in resistance units; pulmonary arteriolar resistance ≒ (mean

pulmonary arterial pressure − mean pulmonary capillary wedge pressure) cardiac output in resistance units.

Results

The hemodynamic data obtained at rest and during exercise before and after administration of perhexiline are summarized in Table I and Figures 1 and 2.

Fifteen of the 16 patients had angina during exercise before administration of perhexiline. In one patient exercise was terminated because 2 mm S–T segment depression occurred before development of chest pain.

Hemodynamic changes in all patients (Fig. 1): After administration of perhexiline, neither resting heart rate, mean systemic pressure, systolic ejection period, or their product changed significantly. Comparison of mean values during exercise (Fig. 1) demonstrated a smaller increase in heart rate (43.5 ± 4.0 [standard error of the mean] versus 32.1 ± 2.7 beats/min, $P < 0.004$) in all patients studied as the peak heart rate achieved was lessened during administration of perhexiline (113.1 ± 5.2 to 103.8 ± 3.2, $P < 0.05$); systemic pressure and systolic ejection period values were not significantly altered. Diastolic pressure-time index increased 29 percent ($P < 0.01$), whereas the diastolic pressure-time/tension-time ratio increased 36 percent ($P < 0.05$). The responses of left ventricular stroke work index and filling pressure during exercise before and after administration of perhexiline are summarized in Figure 2. The exercise stroke work index/filling pressure relation increased in all but one patient after treatment with perhexiline. During exercise, left ventricular stroke work index increased 22 percent ($P < 0.02$) and left ventricular filling pressure declined 49 percent ($P < 0.02$), thus indicating improved left ventricular performance. Neither pulmonary arteriolar nor systemic vascular resistance values were altered by administration of perhexiline.

Angina vs. angina-free group: According to their pain response to exercise at restudy, during treatment with perhexiline, the patients were classified into two groups (Table II). The angina group was composed of four subjects whose angina was not completely alleviated by administration of perhexiline. Exertional angina recurred in these four patients although it was less severe and delayed in two. The angina-free group consisted of the remaining 12 patients in whom perhexiline was completely effective in preventing effort angina. With perhexiline, these patients could perform work without angina for considerably longer periods than before treatment.

Differences are apparent between the groups, the angina-free patients achieving a greater heart rate (Table II) than the angina group during the control exercise period. Perhexiline modified peak heart rate achieved with identical exercise to a greater extent in the angina-free group (−10.3 percent, $P < 0.04$) than in the angina group (−1 percent, not significant); the mean peak heart rate and pressure reached by the angina-free patients was 105.3 beats/min and 126.1 mm Hg, respectively, compared with 117.4 beats/min and 128.2 mm Hg before treatment with perhexiline. The angina group achieved a heart rate of 99.2 beats/min and systemic pressure of 122.7 mm Hg compared with 100.2 beats/min and 113.2 mm Hg with exercise before treatment with perhexiline. Accordingly, tension-time index was lower (4,229 vs. 3,805 mm Hg sec/min) in the angina-free patients for an identical amount of exercise since the duration of systolic ejection did not increase. The exercise-related tension-

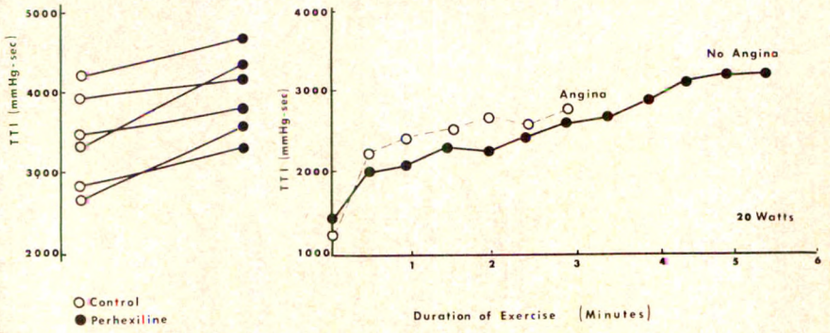

FIGURE 3. Effect of perhexiline administration on response of tension-time index (TTI) to exercise in six angina-free patients. **Left,** values during exercise-induced angina (O) and after perhexiline (●), when exercise was limited by fatigue. **Right,** effects of exercise on tension-time index before **(dotted line)** and after perhexiline **(solid line)** in a 53 year old patient whose response was typical of this group. With perhexiline he exercised for almost 3 additional minutes, achieving a higher tension-time index without angina before he was limited by fatigue.

time index increase declined 22 percent in the angina-free patients but only 7 percent in the angina group. This difference was significant ($P < 0.05$). The diastolic pressure-time index increased (18.1 ± 1.6 to 24.7 ± 1.6 mm Hg sec, $P < 0.01$) during exercise after perhexiline as the diastolic pressure-time/tension-time ratio increased 38 percent ($P < 0.05$) in the angina-free patients. By comparison, in the angina group diastolic pressure-time index and diastolic pressure-time/tension-time ratio showed nonsignificant changes of 16.7 and 10.5 percent, respectively, during exercise after treatment with perhexiline.

After these measurements made at the same intensity and duration of exercise, the angina-free patients continued to exercise for an average of 5.2 minutes, compared with 3.1 minutes before treatment with perhexiline. During this higher level of stress, six patients achieved greater tension-time indexes without experiencing angina than they reached before perhexiline (Fig. 3) as their effort was now limited by fatigue (four patients) or dyspnea (two patients).

Resting left ventricular filling pressure values were normal (13 mm Hg or less) in all but two patients, one in each group. Before treatment, a precipitous increase in left ventricular filling pressure was observed in each group during exercise at angina (from 11.6 to 27.9 mm Hg in angina-free patients and 11.3 to 23.5 mm Hg in the angina group) (Table II). After treatment with perhexiline, the angina-free patients had a more marked reduction (44 percent, $P < 0.04$) in left ventricular filling pressure at the same level of exercise than the angina group (7.8 percent decrease; not significant). The cardiac index increment during exercise, was not significantly altered by treatment with perhexiline in either group. Perhexiline caused no depression of left ventricular work index or mean systolic ejection rate during exercise (Table II).

No major side effects or complications occurred during this short-term trial or in relation to the investigational procedures. Early in the treatment period, two patients noted very mild, transient (1 to 2 days) lightheadedness unrelated to changes in blood pressure or pulse rate.

Follow-up results: Fourteen of the 16 patients reported less frequent episodes of angina and ability to perform more strenuous physical activity before angina was precipitated; 2 patients noted no change compared with placebo at this fixed dose. The average number of anginal episodes and the amount of nitroglycerin consumed per month were significantly ($P < 0.05$) reduced, from 46 ± 6 to 19.8 ± 6.0 episodes/month and 27 ± 3 to 9 ± 2.0 tablets/month, respectively. Serial resting 12 lead electrocardiograms were unchanged when compared with those taken at the initial evaluation before treatment with perhexiline, and no history indicating that myocardial infarction had occurred between the two studies was obtained. Perhexiline significantly ($P < 0.01$) prolonged the duration of exercise (301 ± 18 seconds) compared with the change after placebo (212 ± 20 seconds) as peak heart rate was reduced.

Discussion

Our results with orally administered perhexiline, in doses well tolerated by patients with coronary artery disease, are in agreement with those of preliminary studies[4–6] and support the evidence that perhexiline increases exercise tolerance of patients limited by angina pectoris. Increased effort tolerance was associated with a reduction in heart rate during identical levels of exercise of approximately 10 percent in the patients who were angina-free after treatment with perhexiline. This change was not offset by changes in the response of arterial blood pressure or the duration of systole. Thus, perhexiline reduces the myocardial oxygen cost of a given level of exercise.

Perhexiline and ventricular performance during exercise: That perhexiline alters ischemic left ventricular function is indicated by prevention of the precipitous abnormal increases in left ventricular filling pressure observed during exercise. Left ventricular dysfunction was reduced, as evidenced by a shift to the left and upward of the stroke work/filling pressure relation (Fig. 2). By contrast, patients without relief of angina had increases in heart rate and left ventricular filling pressure with exercise during perhexiline therapy similar to those of the control exercise period (Table II). These results also added objective confirmation of the ability of perhexiline to alter or prevent myocardial ischemia. The finding that the tension-time index increased significantly in six of the angina-free patients during increased exercise stress may represent an increase in myocardial oxygen consumption during perhexiline therapy (Fig. 3). Within the limitations of this index, as emphasized by others,[15] these results can be interpreted to indicate that perhexiline enhances myocardial oxygen delivery in some patients with coronary artery disease.

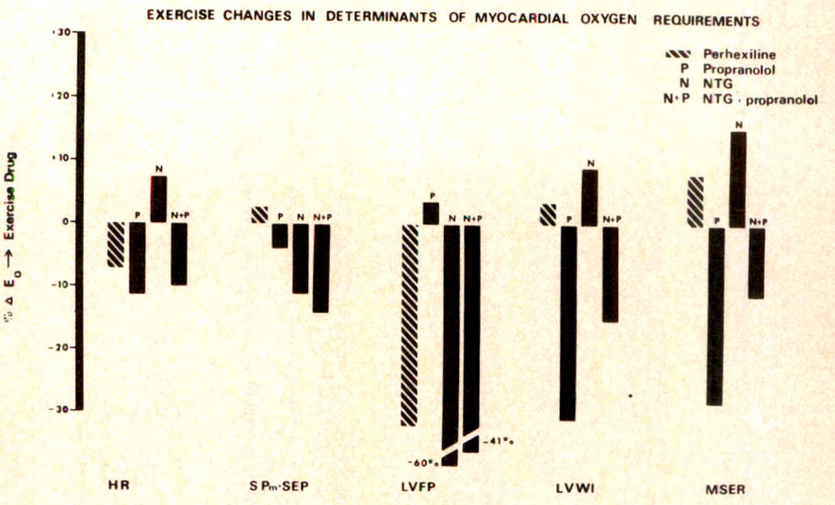

FIGURE 4. Comparison of the effects of perhexiline **(striped bars)**, propranolol (P), nitroglycerin (N) and nitroglycerin and propranolol (N + P) on several hemodynamic determinants of myocardial oxygen consumption. The percent difference during exercise (pre to post drug administration) for each function is indicated on the vertical axis. Abbreviations on the horizontal axis are the same as in Table II. Note that perhexiline has actions that resemble those of propranolol (reduction of exercise heart rate) and nitroglycerin (enhanced left ventricular work index and reduced left ventricular filling pressure) without undesirable oxygen-wasting effects (increased left ventricular filling pressure with propranolol and increased heart rate with nitroglycerin).

In spite of the assumptions involved in this index, support for the latter suggestion was observed through the increase in a major determinant of myocardial blood supply, namely the diastolic pressure-time index.

Others[12,16] have shown that changes in ventricular performance and myocardial blood flow distribution can be predicted by using a ratio of the diastolic pressure-time index (to estimate subendocardial flow) and the tension-time index (to estimate cardiac oxygen needs). Exercise produces tachycardia and enhances contractility increasing myocardial oxygen requirements; at the same time, although systemic pressure increases, diastole is shortened. In patients with coronary artery disease left ventricular diastolic pressure also increases and these needs are only partially met by increased coronary blood flow resulting from coronary vasodilatation. The net effect limits the potential increase in flow produced by a given degree of coronary dilatation making it inadequate to meet simultaneously increasing oxygen requirements. At this time subendocardial flow is dependent on the relation between diastolic coronary-left ventricular pressure gradients and the time available for perfusion (diastolic pressure-time index). In our study diastolic pressure-time shortened critically with exercise stress but was increased during exercise after perhexiline therapy. A significant increase also occurred in the diastolic pressure-time/tension-time ratio after administration of perhexiline during exercise. These changes imply an increase in subendocardial blood flow relative to oxygen requirements and suggest an additional explanation for the prevention of angina and impaired ventricular performance during stress after perhexiline therapy.

Direct cardiac effects of perhexiline: Evidence for both direct and extracardiac effects of perhexiline has been derived from previous studies in laboratory animals using direct infusion of perhexiline. Hudak et al.[1] demonstrated large decreases in coronary, pulmonary and systemic vascular resistance and heart rate after administration of 1 and 3 mg/kg body weight in anesthetized dogs. Reflex vasoconstriction and tachycardia did not occur. In these studies perhexiline did not alter the heart rate effects of isoproterenol, and propranolol did not affect the changes in arterial pressure or coronary flow that followed treatment with perhexiline. Bilateral vagotomy did not modify either the hypotension or negative chronotropic actions of perhexiline. Directionally similar but quantitatively less reduction in coronary and systemic resistances was reported by Cho et al.[2] at low and high perfusion rates in a right heart bypass preparation. They also observed a fall in cardiac rate, work and oxygen consumption. The heart rate effect was not altered by vagotonic, cholinergic or adrenergic blockade.[17]

In acute studies in six unanesthetized patients with severe coronary atherosclerosis and angina pectoris, Rowe et al.[18] noted a significant decline in resting heart rate after a 40 to 60 mg right heart infusion over 3 to 5 minutes. No change was noted in mean systemic blood pressure. Cardiac output also decreased with associated reduction of left ventricular work, whereas mean pulmonary arterial pressure was unchanged. These workers suggested that the effect of perhexiline was related to dose and route of administration. Hemodynamic measurements during exercise have not been reported.

In our study orally administered perhexiline did not induce systemic arterial hypotension or significant decreases in peripheral resistance, yet its cardiac action persisted. No evidence for reduced cardiac work as suggested by prior studies was demonstrated. It is likely that the observed responses in our unanesthetized patients after treatment with perhexiline are more complex than merely direct vascular effects because of each vascular bed's intact autoregulatory capacity. The sensitivity to perhexiline of dog heart muscle and peripheral vessels probably differs from that of man. In addition, the effects of perhexiline on hemodynamic variables may be different during its continued absorption from the gastrointestinal tract than after bolus intracardiac infusion. Considering this compound's long excretion half-life[9] the tissue level of the drug must be very different after days of

continuous oral administration from the level during bolus injection studies.

Mechanism of antianginal and hemodynamic effects of perhexiline: Perhexiline-induced changes in cardiac function differ from responses described with other antianginal agents. Data previously reported[14] from similar studies conducted in our laboratory after nitroglycerin, propranolol and their combination are compared with perhexiline in Figure 4. Nitroglycerin decreases left ventricular filling pressure during exercise but also reduces cardiac output, ejection time and systemic pressure, acting to diminish oxygen requirements. However, baroreceptor-mediated increases in heart rate and contractility tend to have opposite effects on myocardial oxygen consumption. Improved left ventricular function during exercise (increased stroke work index/left ventricular filling pressure ratio) with administration of perhexiline resembles responses observed with nitroglycerin but without decreased coronary filling pressure or the additional oxygen costs of reflex tachycardia.

Although perhexiline is not a beta adrenergic blocking agent,[1] the reduction in exercise-induced tachycardia is similar to that observed with propranolol. However, cardiac output and ejection rate also decline as the duration of systole is prolonged after propranolol with equivalent abnormal increases in left ventricular filling pressure during exercise.[14] Perhexiline has the beneficial oxygen-sparing effect of propranolol with respect to alteration of exercise heart rate, without its undesirable myocardial depression (decreased stroke work index/left ventricular filling pressure). The hemodynamic response during treatment with perhexiline more closely resembles that observed with use of both nitroglycerin and propranolol. This combination favorably alters left ventricular function during exercise by increasing stroke work while reducing left ventricular filling pressure.[14] Blockade of reflex-mediated increases in heart rate and contractility lessens oxygen requirements. Accordingly, perhexiline affords very similar ventricular functional responses while some persisting, less desirable properties (depressed left ventricular work and mean systolic ejection rate) of the former drug combination are absent.

Conclusion

The purpose of this study was to assess whether orally administered perhexiline has a measurable influence on clinical and hemodynamic responses to exercise in patients with angina pectoris. Our data clearly support the initial findings of others that this drug is of value in preventing effort-induced angina pectoris. This beneficial effect, persisting 4 hours after administration, relates to hemodynamic actions that include reduced exercise tachycardia, prolongation of the diastolic pressure-time interval and reduction of ischemia-related left ventricular dysfunction. Although the exact mechanism of the antianginal and hemodynamic actions of perhexiline has not been determined, our study provides indirect support that such responses result from a primary cardiac effect, possibly related to enhanced myocardial oxygen delivery. The improvement observed suggests that perhexiline is a useful addition to available means for prophylaxis of angina pectoris.

Acknowledgment

We thank Dr. William J. Hudak of Merrell-National Laboratories, Cincinnati, Ohio for kindly supplying the perhexiline and placebo used in this study. We are also grateful to Mrs. Kathy Dennish, who provided valuable assistance throughout this investigation.

Myocardial Infarction After Exercise-Induced Electrocardiographic Changes in a Patient with Variant Angina Pectoris

R. LELDON SWEET, MD
L. THOMAS SHEFFIELD, MD

Birmingham, Alabama

The electrocardiographic response to stress testing varies considerably in patients with variant angina pectoris: no change in the S–T segment as well as S–T segment depression and elevation have been observed. This report describes a patient with a resting ST–T abnormality that reverted to normal appearance with exercise. However, the patient experienced severe chest pain shortly after discontinuing exercise testing, and an electrocardiogram showed evidence of acute anterolateral infarction. The possible implications of such electrocardiographic changes are discussed.

Since Prinzmetal's preliminary report[1] in 1959 on a group of patients with a variant form of angina pectoris, much interest has been generated in methods of diagnosing this lesion. The early papers reported that chest pain and its associated electrocardiographic changes occurred primarily at rest or with ordinary exercise. In Prinzmetal's original study,[1] exercise testing (Master two-step technique) failed to provoke pain or the characteristic S–T segment elevation noted in these patients during spontaneously occurring chest pain. Either there was no S–T deviation with exercise, or S–T depression appeared. Since S–T segment depression after exercise also occurs in patients with the classic form of angina pectoris and in some with asymptomatic coronary artery disease, exercise tests have been thought to be of little value in diagnosing the variant form of angina. More recently Kemp[2] described a patient with variant angina who manifested intermittent S–T segment elevation with treadmill stress testing, and suggested that such testing may be a diagnostic aid in cases of variant angina.

This report presents a patient with atypical chest pain and resting electrocardiographic abnormalities that reverted to normal appearance with exercise. However, evidence of acute myocardial infarction developed shortly after stress testing was discontinued.

Case Report

A 61 year old white male postmaster was referred for evaluation of chest pain he had experienced for approximately 3 months before admission. The pain, located in the left precordium, was characterized as "squeezing." It generally occurred at rest and was not precipitated or aggravated by exercise, emotional upset or sexual intercourse. The patient stated that he was an avid bird hunter and could follow his dogs for 5 to 6 miles a day in cold weather without pain or undue shortness of breath. He denied orthopnea, paroxysmal nocturnal dyspnea, dependent edema or palpitations. He stated that the pain occurred four to five times a day, never lasted longer than 30 minutes and was generally relieved by nitroglycerin in 3 to 4 minutes. He had received intermittent treatment for hypertension for approximately 25 years and also borderline diabetes, treated by diet alone. He had smoked one pack of cigarettes a day for approximately 40 years and denied excessive alcohol intake. He had no known lipid abnormalities and no history of gouty arthritis. There was no premature coronary artery disease or diabetes in his immediate family

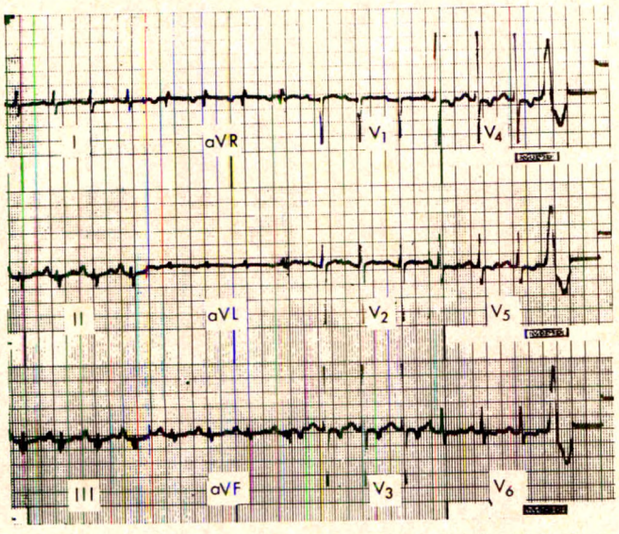

FIGURE 1. Standard 12 lead electrocardiogram obtained before exercise testing (paper speed 25 mm/sec).

but two siblings had hypertension, one sustaining a cerebrovascular accident. Medications at the time of admission included methyldopa and amitriptyline.

Physical examination revealed a tall, rather obese white man with a blood pressure of 180/105 mm Hg in both arms; heart rate was 76 beats/min and regular. Funduscopic examination revealed moderate arteriolar narrowing and arteriovenous nicking without hemorrhages, exudates or microaneurysms. He had no visible xanthomas or arcus senilis. Cardiovascular examination was entirely normal except for the auscultatory finding of a fourth sound gallop.

Initial chest roentgenograms with cardiac fluoroscopy revealed a normal cardiothoracic ratio without specific chamber enlargement. There was a small area of calcification in the region of the left anterior descending coronary artery. The admission electrocardiogram revealed a sinus rhythm with a normal QRS axis, slightly depressed S–T segments and T wave inversion in leads V_4 through V_6 (Fig. 1). QRS voltage did not fulfill the criterion for left ventricular hypertrophy. Admission laboratory data included normal values for hematocrit, blood urea nitrogen and serum electrolytes. Uric acid was slightly increased (9.4 mg/100 ml). Results of fasting and 2 hour postprandial blood sugar determinations were normal. Serum cholesterol was 198 and triglyceride 117 mg/100 ml.

During the first two days the patient had no spontaneous episodes of chest pain. On the third hospital day he was subjected to a graded exercise test[3] (Sheffield-Reeves) using the stages of Bruce and McDonough.[4] Medications at that time included methyldopa, 250 mg four times a day, and hydrochlorothiazide, 50 mg once daily. In a fasting state with normal serum potassium, he achieved a maximal heart rate of 170 beats/min after 10 minutes and 30 seconds on the treadmill. This response was above that predicted for his age and prior activity level using the criteria of Bruce to assess functional aerobic capacity with the multistage treadmill test. The patient experienced no chest discomfort, nausea or undue leg discomfort. The previously described ST–T changes present at rest normalized with exercise; the S–T segment became isoelectric and the T wave reverted to a normal upright appearance (Fig. 2).

Approximately 10 minutes after discontinuation of stress testing, while still in the exercise laboratory, he began to experience nausea, vomiting and diaphoresis followed by left anterior precordial pain that was increasingly severe and prolonged. Repeated electrocardiograms revealed S–T segment elevation extending from leads V_2 through V_6; serial tracings and serum enzyme determinations confirmed the presence of an extensive anterolateral myocardial infarction (Fig. 3). His hospital course was complicated by recurrent arrhythmias and persistence of S–T segment eleva-

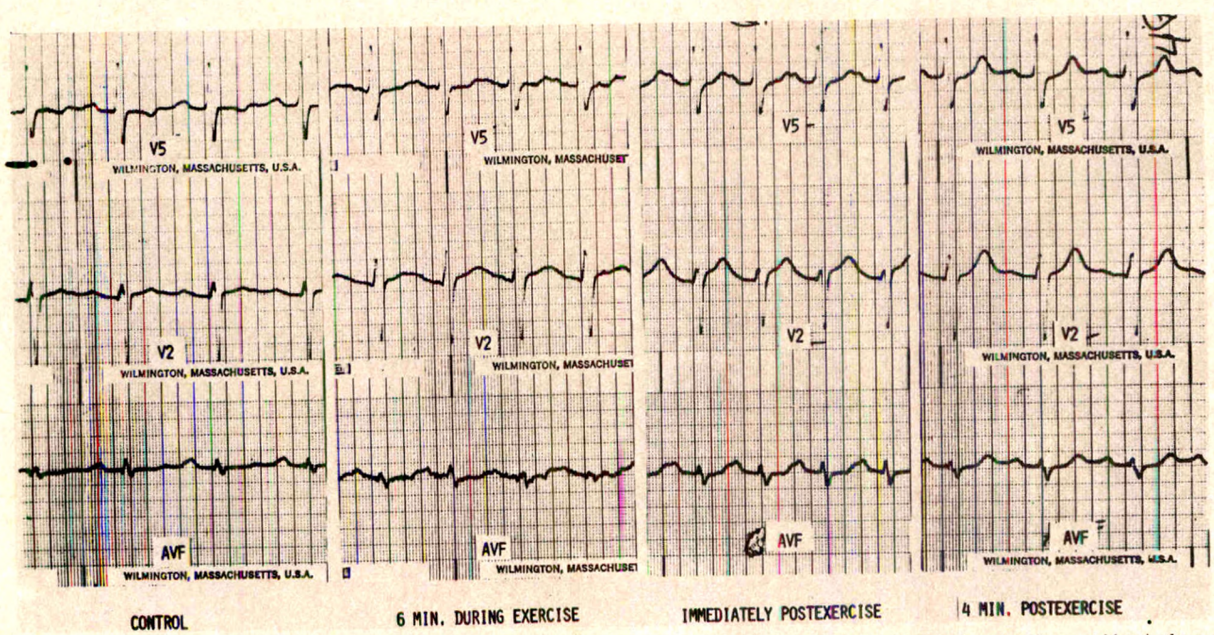

FIGURE 2. Representative sections of exercise monitoring leads (V_5, V_2 and aVF) obtained with the patient in the standing position before exercise, during the 6th minute of exercise, immediately after and 4 minutes after exercise (paper speed 50 mm/sec).

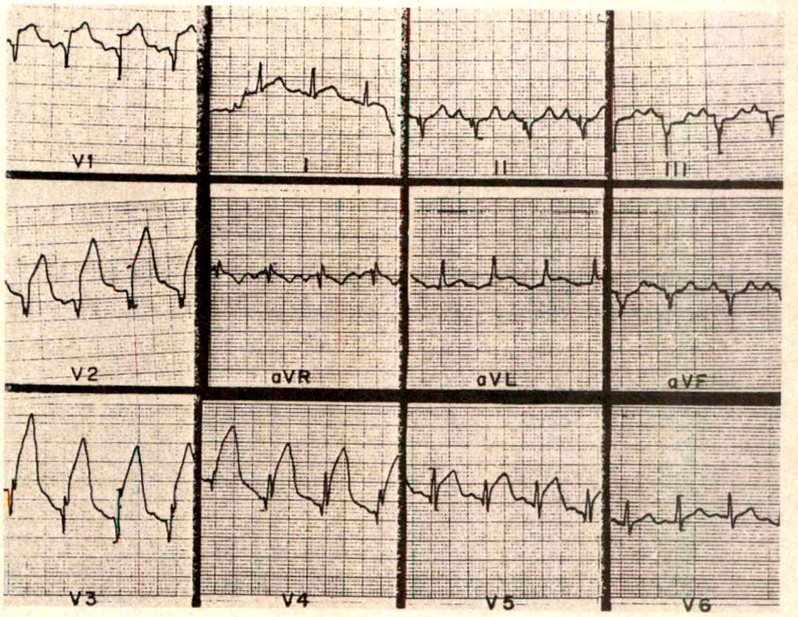

FIGURE 3. Standard 12 lead electrocardiogram obtained after the onset of chest pain 20 minutes after exercise (paper speed 25 mm/sec).

tion (Fig. 4). Subsequent evidence of paradoxic pulsation was found on physical and fluoroscopic examination. He was subsequently discharged symptom-free on the 32nd day after infarction.

During the 6 months after discharge the pattern of his chest pain has changed; it is now usually precipitated by exertion of only one to two blocks of walking. Cardiac catheterization was performed 10 months after infarction. Left ventricular biplane angiograms revealed ventricular enlargement with anterior wall akinesis. Coronary angiograms revealed proximal occlusion of the left anterior descending artery just distal to the first septal branch. The right coronary artery was dominant and showed a 90 percent stenosis in its proximal third and a good distal vessel. The left main and circumflex arteries were free of detectable lesions.

Discussion

As in the case presented by Kemp,[2] a resting electrocardiogram could not be obtained during an episode of pain. However, the quality, location, periodicity, lack of precipitation with exercise and response to nitroglycerin were such that a diagnosis of variant angina pectoris seems most appropriate.

As with Kemp's patient and those previously presented by Prinzmetal et al.[1] there was a total absence of chest pain during vigorous exertion. Thus, if treadmill testing is to be used in the diagnosis of variant angina, one must rely heavily on interpretation of ST–T changes since subjective symptoms will proba-

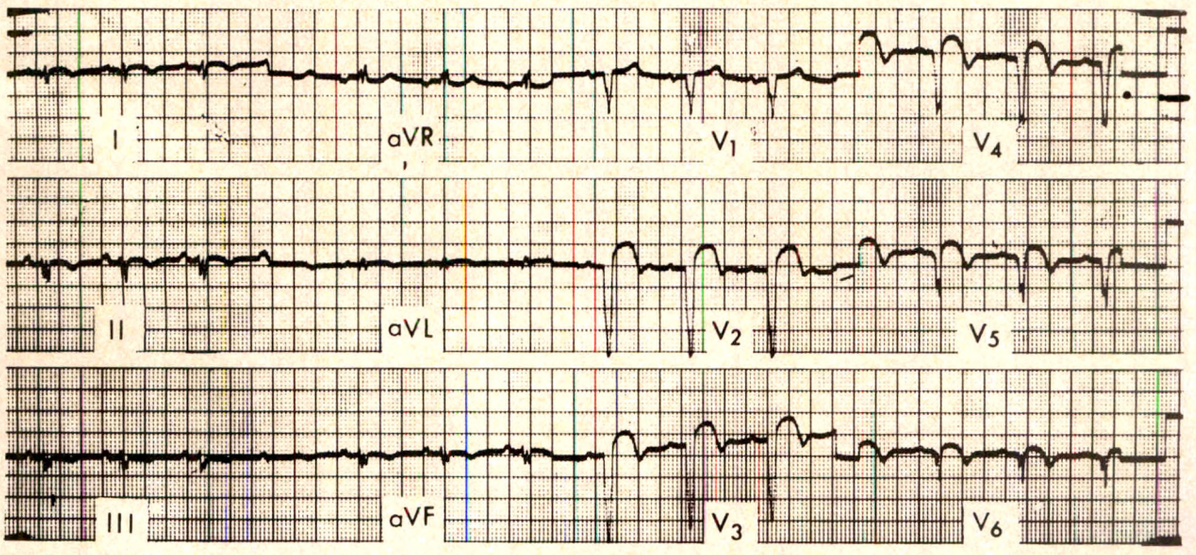

FIGURE 4. Standard 12 lead electrocardiogram obtained 17 days after myocardial infarction, revealing persistent S–T segment elevation (paper speed 25 mm/sec).

bly be absent. At this point considerable difficulty is encountered. The conversion of a normal control tracing to one showing an ischemic S–T segment in response to stress testing is not specific for myocardial hypoxia and may be produced by left ventricular hypertrophy, left ventricular overload without detectable hypertrophy, intraventricular conduction defects, digitalis glycosides as well as hyperventilation.[3,5] The standard criteria are based on S–T segment depression (from a previous isoelectric S–T segment) initiated by J point depression of 0.1 mv or more and followed by an S–T segment that is flat or downsloping (slope of less than +1 mv/sec).[3] S–T segment elevation with exercise has also been shown to occur in patients with significant coronary artery disease. In the study by Fortuin and Friesinger,[6] 11 of 12 patients with exercise-induced S–T segment elevation were found at coronary angiographic examination to have total or near total occlusion of a major coronary artery. Manvi and Ellestad[7] recently reported data on patients with a ventricular aneurysm and a normal S–T segment at rest who subsequently manifested S–T segment elevation during maximal treadmill testing. Their patients were found to have large apical aneurysms with major obstruction in the left anterior descending coronary artery. Kemp's patient with variant angina also demonstrated S–T segment elevation with treadmill testing, and angiographic studies revealed severe stenosis of both the proximal circumflex (98 percent) and proximal left anterior descending (90 percent) coronary arteries.

Hence, in patients with isoelectric S–T segments at rest, it has been shown that either significant S–T segment depression or elevation with exercise correlates highly with significant coronary artery disease.[6,8,9] In patients with S–T segment abnormalities at rest, interpretation becomes difficult.[10] In patients with typical angina pectoris, the subjective sensation of typical chest pain with exertion can be used as an end point for terminating stress testing. However, in patients with variant angina, pain may be absent throughout the testing period. To compound the problem further, Prinzmetal et al., in their original papers,[1,11] noted that patients with resting electrocardiographic abnormalities may show apparent reduction of these changes during pain. Although others[12] have noted both normalization of a previously depressed S–T segment to the base line and the associated return of an inverted T wave to an upright position, these changes have not been assessed in detail. In our patient, such changes were the harbingers of later frank S–T segment elevation indicating extensive myocardial infarction.

Clinical Implications

Exercise testing is being used more extensively for both diagnostic and prognostic evaluation of patients. Patients with atypical chest pain are particularly likely to undergo such testing. A recent survey of 73 medical centers performing such evaluation indicates that these procedures are safe in most patients when properly administered (mortality 1/10,000 tests or 0.01 percent; morbidity 2.4/10,000 tests or 0.02 percent).[13] However, patients with atypical chest pain revealed by careful questioning to have probable variant angina may be at particularly high risk for maximal or submaximal stress testing. We believe the following considerations should be kept in mind when evaluating such patients:

1. Chest pain, a critical signal for terminating stress testing, is absent in the majority of these patients despite markedly increased myocardial oxygen demands at maximal or near maximal treadmill testing.
2. S–T segment changes, which must be relied upon as an index of ischemia in the absence of pain, are unpredictable in this group of patients.
3. Normalization of previously abnormal ST–T changes during exercise may indicate progressive ischemia, as illustrated in our case, and may offer a false sense of security to the unsuspecting.
4. Since the pain most frequently occurs at rest or during ordinary exertion or at night, a more physiologic and less hazardous approach would be the use of continuous Holter monitoring to demonstrate the typical S–T segment changes that occur during these periods.[14]
5. Because of the grave prognosis that has been demonstrated in this group[15] and because of the previously mentioned difficulties inherent in some of the usual diagnostic procedures, it would seem advisable to proceed to early angiographic studies in an attempt to obtain a more definitive diagnosis. This procedure may be particularly useful not only in defining static areas of obstruction, but also in demonstrating coronary arterial spasm, as found by Dhurandhar et al.[16] during an episode of pain. This finding is of particular interest in light of Prinzmetal's original hypothesis that arterial spasm is the possible cause of pain in this group of patients.

INSTRUCTIONS FOR AUTHORS

The editors and publishers of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- **Address manuscript** to Simon Dack, MD, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- **Submit two copies** of all elements of the article: text, references, legends, tables and figures.
- **Arrange the paper** in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- **Number all pages** in above sequence, beginning with title page as 1, abstract as 2, etc.
- **Type all matter:** (1) on 8½ × 11 opaque white bond paper; (2) in duplicate; (3) on **one side** of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- **Number title page** as page 1.
- **Include first names,** degrees and, where applicable, FACC for all authors.
- **Insert at bottom:** name and address of institution from which work originated plus information about grants.
- **Add at bottom** the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- **Limit words as follows:** 100 to 250 words for major articles; 50 to 100 words for case reports.
- **Add at end of abstract:** an alphabetical list of 2 to 6 key words and subjects for indexing.

THE TEXT

- **Number pages** in sequence after abstract.
- **Type in duplicate;** double-space.
- **Do not use abbreviations** such as SVC, WPW: write out; superior vena cava, Wolff-Parkinson-White.

Abbreviate measurements (mm, kcal and the like) as recommended in the Style Manual for Biological Journals, American Institute of Biological Sciences, 3900 Wisconsin Avenue, N.W., Washington, D. C.

- **Cite in numerical** order every reference, figure and table. (Order of mention in text **determines the number** given to each.)
- **Place acknowledgments** at end of text, before references.

THE REFERENCES

- **Type in duplicate;** double-space.
- **Place immediately** after text, and number pages in sequence after text page numbers.
- **Number the references** in order in which they are mentioned in text.
- **Follow the general** arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- **Start at top** of new page.
- **Type in duplicate;** double-space.
- **Number pages** in sequence after last page of references.
- **Identify at** the end of each legend and **in alphabetical order** all abbreviations in the figure described.

THE TABLES

- **Start each** table at top of new page.
- **Type in duplicate;** double-space.
- **Number pages** in sequence after last page of legends.
- **Give each table** a number (in roman numerals: Table I, II, etc.) and a title. Number the tables in order in which they are mentioned in the text.
- **Provide a footnote** to each table—identifying **in alphabetical order** all abbreviations used.

THE FIGURES

- **Submit 2 glossy prints** (not originals) of each photo and drawing.

Please note that art work of published articles will not be returned.

- **Use black ink** for all charts (line drawings). Make decimals, broken lines, etc. strong enough for reproduction.
- **Use arrows** to designate special features.
- **Crop photomicrographs** to show only essential field.
- **Identify figures** on back by number and author's name.
- **Number figures** in order in which they are mentioned in the text.
- **Indicate top** of each figure.
- **Submit written permission** from publisher and author to reproduce any previously published figures.
- **Limit figures** to number necessary for clarity. The publisher allows a limited sum toward reproduction.

tolerance to exercise improved for angina patients

INDICATIONS: For the prophylaxis and long-term management of patients with frequent or recurrent anginal pain and reduced exercise tolerance associated with angina pectoris, rather than for the treatment of the acute attack of angina pectoris, since its onset of action is somewhat slower than that of nitroglycerin.

PRECAUTIONS: As with other effective nitrites, some fall in blood pressure may occur with large doses. Caution should be observed in patients with a history of recent cerebral hemorrhage, because of the vasodilatation which occurs in the area. Although therapy permits more normal activity, the patient should not be allowed to misinterpret freedom from anginal attacks as a signal to drop all restrictions.

SIDE EFFECTS: No serious side effects have been reported. As with nitroglycerin or other effective nitrites, temporary vascular headache may occur during the first few days of therapy. This can be controlled by temporary dosage reduction in order to allow adjustment of the cerebral hemodynamics to the initial marked cerebral vasodilatation. These headaches usually disappear within one week of continuous therapy but may be minimized by the administration of analgesics such as Empirin® Compound.

Mild gastrointestinal disturbances occur occasionally with larger doses and may be controlled by reducing the dose temporarily.

SUPPLIED: 10 mg. chewable tablets. Bottles of 100. Also 5, 10 and 15 mg. scored tablets in bottles of 100. 10 mg. scored tablets also supplied in bottles of 1000.

Also available: Cardilate-P brand Erythrityl Tetranitrate with Phenobarbital (Warning: may be habit-forming).

Cardilate®
(erythrityl tetranitrate)

chewable tablets 10 mg.
t.i.d. or q.i.d. (p.r.n.)
an effect appears in approximately 5 minutes
—total duration of effect up to 4 hours.

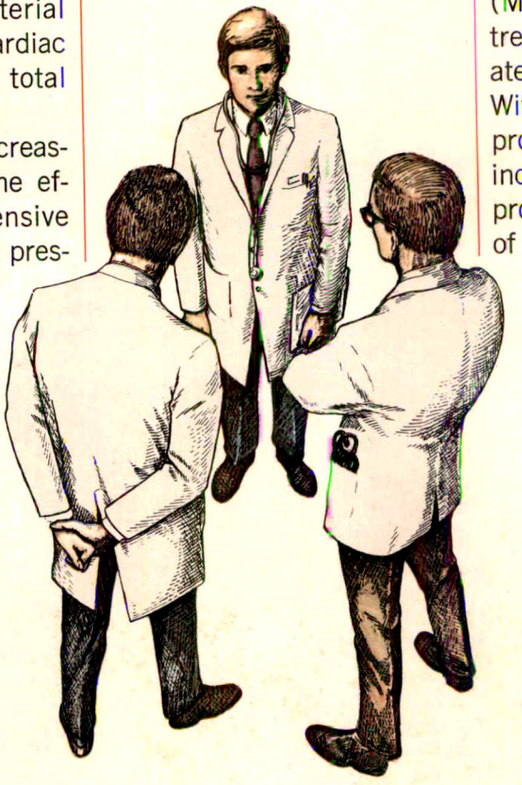
The more physicians consider the hemodynamics of lowering blood pressure...

Most physicians now agree on the importance of reducing blood pressure in the hypertensive patient. But high blood pressure exists, of course, only as part of a complete clinical picture. The hemodynamic profile of well-established essential hypertension is characterized by elevated arterial blood pressure, normal cardiac output, and increased total peripheral resistance.

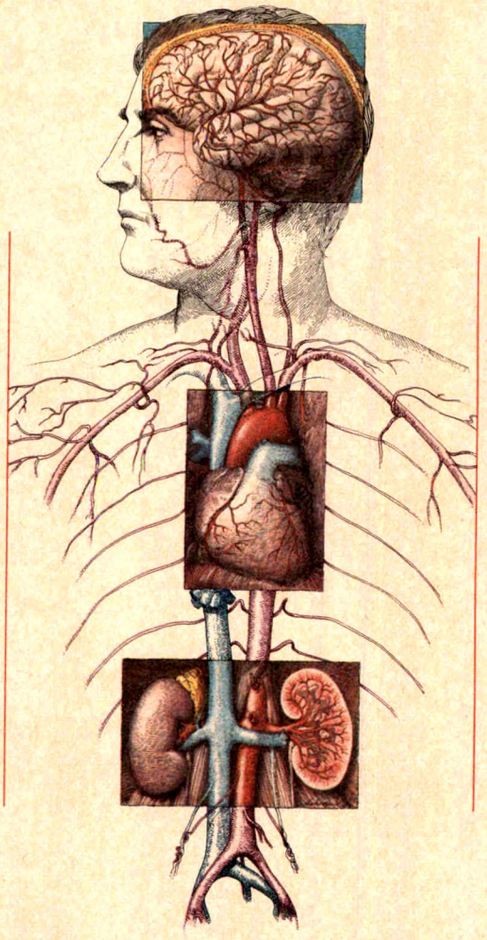
And so, physicians are increasingly concerned with the effects of an antihypertensive agent not only on blood pressure itself but also on the hemodynamic pattern—in short, with the total effect of the drug. *Does* it indeed help lower blood pressure effectively? *Is* peripheral resistance reduced? *Are* cardiac output and renal functions maintained? And, also, is there likely to be drug-induced postural hypotension serious enough to pose a threat to the patient's cerebrovascular status?



With this emphasis on overall drug performance has come a growing reliance on ALDOMET® (Methyldopa, MSD) in the treatment of sustained moderate hypertension.

With its unique hemodynamic profile, ALDOMET has drawn increasing attention and approval from physicians. First, of course, for its efficacy in

the more physicians rely on this unique antihypertensive



lowering blood pressure. But there are other considerations as well. Cardiac output is usually maintained with no cardiac acceleration; in some patients the heart rate is actually slowed. Peripheral resistance is apparently reduced. ALDOMET does not usually compromise existing renal function; it generally does not reduce renal blood flow, glomerular filtration rate, or filtration fraction. And ALDOMET usually does not cause symptomatic postural or exercise hypotension.

Some patients on continuous methyldopa therapy may develop a positive direct Coombs test. For more details, see the brief summary of prescribing information.

Contraindicated in active hepatic disease and known sensitivity to the drug. Not recommended in pheochromocytoma or pregnancy. It should be used with caution in patients with a history of liver disease or dysfunction. Discontinue the drug if fever, abnormal liver function, jaundice, or acquired hemolytic anemia occurs.

In most cases of sustained moderate hypertension

TABLETS, 250 mg

ALDOMET®
(METHYLDOPA | MSD)

smoothly lowers blood pressure

For a brief summary of prescribing information, please see following page.

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

In most cases of sustained moderate hypertension

TABLETS, 250 mg

ALDOMET®
(METHYLDOPA | MSD)

smoothly lowers blood pressure

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; known sensitivity. Not recommended in pheochromocytoma. Unsuitable in mild or labile hypertension responsive to mild sedation or thiazide therapy. Use cautiously in patients with history of previous liver disease or dysfunction.

Warnings: Acquired hemolytic anemia has occurred rarely in association with therapy with methyldopa. Should clinical symptoms indicate the possibility of anemia, hemoglobin and/or hematocrit determinations should be performed. If anemia is present, appropriate laboratory studies should be done to determine if hemolysis is present. Evidence of hemolytic anemia is an indication for discontinuation of the drug. Discontinuation of methyldopa alone or the initiation of adrenocortical steroids usually results in a prompt remission of the anemia. Rarely, however, fatalities have occurred.

Some patients on continued therapy with methyldopa develop a positive direct Coombs test; incidence reported has averaged between 10% and 20%. It rarely occurs in first six months of therapy, and if not seen within twelve months, is unlikely to develop with continued administration. Positive Coombs test is dose-related; lowest incidence occurs in patients on 1 g methyldopa or less per day. Reversal of the positive Coombs test occurs within weeks to months after discontinuation of methyldopa. Prior knowledge of a positive Coombs reaction aids in evaluation of cross match for transfusions. Patients with positive Coombs tests at time of cross match may exhibit incompatible minor cross match. When this occurs, an indirect Coombs test should be performed. If negative, transfusion with blood otherwise compatible in the major cross match may be carried out. If positive, advisability of transfusion with blood compatible in major cross match should be determined by hematologist or expert in transfusion problems.

Fever has occurred within first three weeks of therapy, sometimes with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first two to three months of therapy. Rare cases of fatal hepatic necrosis have been reported. Liver biopsy in several patients with liver dysfunction has shown microscopic focal necrosis compatible with drug hypersensitivity. Rarely, reversible reduction in leukocyte count with primary effect on granulocytes has been seen; reversible agranulocytosis has been reported. Methyldopa may interfere with measurement of creatinine by alkaline picrate method and of uric acid by phosphotungstate method. When used with other antihypertensive drugs, potentiation of antihypertensive action may occur.

Usage in Pregnancy and Childbearing Age—Not recommended in pregnancy. In women of childbearing age, weigh potential benefits against possible fetal hazards.

Precautions: Perform periodic hepatic function tests and white cell and differential blood counts during first six to twelve weeks of therapy or in unexplained fever. Discontinue if fever, abnormalities in liver function tests, or jaundice appears. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, spuriously high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. Discontinue drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Anesthetics requirements may be reduced; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension may occur after dialysis because methyldopa is removed by this procedure.

Dosage should be limited initially to 500 mg daily when following previous antihypertensive agents other than thiazides. Do not exceed recommended daily dose of 3.0 g. Patients with impaired renal function may respond to smaller doses than patients with normal kidney function. Syncope in older patients has been related to increased sensitivity in those with advanced arteriosclerotic vascular disease; this may be avoided by lower doses. Tolerance occasionally seen either early or late, but more likely between second and third month after initiation of therapy; increased dosage or combined therapy with a thiazide frequently restores effective control.

Adverse Reactions: Sedation, usually transient, may be seen during initial therapy or when dosage is increased. Headache, asthenia, or weakness may be noted as early, transient symptoms. Symptoms associated with effective lowering of blood pressure, including dizziness, lightheadedness, and symptoms of cerebrovascular insufficiency, are seen occasionally. Angina pectoris may be aggravated. Symptoms of orthostatic and exercise hypotension may occur; if symptoms occur, reduce dosage. Bradycardia, nasal stuffiness, mild dryness of mouth, and gastrointestinal symptoms including distension, constipation, flatus, and diarrhea occur occasionally; these can be relieved by reducing dosage. Nausea and vomiting have been reported in only a few patients. Sore tongue or "black tongue," pancreatitis, and inflammation of salivary glands may occur.

Weight gain and edema occur infrequently; if edema progresses or signs of pulmonary congestion appear, discontinue drug. Rarely, urine exposed to air may darken due to breakdown of methyldopa or its metabolites. Other rare reactions include breast enlargement, lactation, impotence, decreased libido, skin rash, mild arthralgia, myalgia, paresthesias, parkinsonism, psychic disturbances including nightmares, reversible mild psychoses or depression, reversible thrombocytopenia, drug-related fever and abnormal liver function studies with jaundice and hepatocellular damage (see **Warnings** and **Precautions**), rise in BUN, and a single case of bilateral Bell's palsy.

Supplied: Tablets, containing 250 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 1000.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486

MSD
MERCK SHARP & DOHME

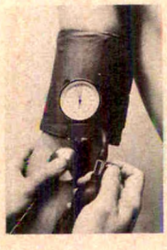
ADDENDUM

Let's make blood pressure "required reading" for all physicians.

With recent estimates that about 23 million Americans have high blood pressure—and that half of them are not even aware of it—detection of the problem in asymptomatic persons has become an issue of national importance.

Family physicians are being urged to take blood pressure readings as a matter of office routine, regardless of the presenting complaint or the reason for the visit. And because many people do not see a family physician for relatively long periods of time, some experts are suggesting that ophthalmologists, gynecologists, dermatologists, orthopedists, psychiatrists, dentists, school nurses, family planning counselors, and other health-care personnel make blood pressure reading a routine part of every examination or consultation.

Of course, a diagnosis of hypertension cannot be made on the basis of a single reading, but routine blood pressure readings can uncover potential trouble in a certain proportion of patients. And when trouble is suggested, further evaluation can be pursued more effectively.



Blood pressure—"required reading" for all physicians.

American offers you a complete line of ECG electrode systems...

ECG monitoring is no place for compromises. That's why American offers you a choice of "no-compromise" electrode systems, each designed for a specific monitoring area.

Stress Test System

This is the first electrode and cable system designed for the rigors of stress test monitoring.

The American Stress Test system minimizes problems with wide or unstable base lines, motion artifact and possible hidden S-T depression.

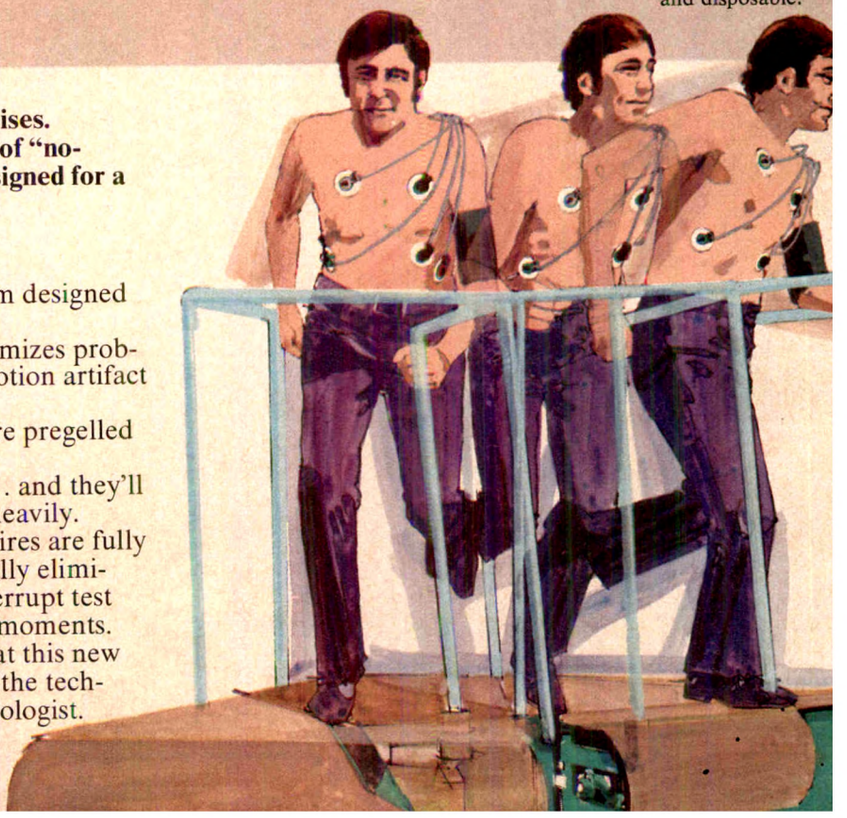
The silver/silver chloride electrodes are pregelled and disposable.

They are quickly and easily applied . . . and they'll stay put, even on patients who perspire heavily.

The quick disconnect cable and leadwires are fully shielded: Electrical interference is virtually eliminated; a damaged leadwire need not interrupt test continuity because it can be replaced in moments.

A demonstration will convince you that this new system can make stress testing easier for the technician and more meaningful to the cardiologist.

(Because of the Stress Test Electrode's special gel formulation, application periods of longer than four hours are not recommended.)



...because there's no such thing as an "all purpose" electrode.

ong Term System

he majority of ICU/CCU's this country now depend on ne American Long Term lectrode system.

There are reasons for this verwhelming acceptance. his silver/silver chloride lectrode is convenient to use nd offers up to seven days of eliable, trouble-free monoring performance.

The things you don't want . . patient skin irritation, notion artifact and wide base nes . . . are the things this ystem invariably eliminates.

The American Long Term lectrode system lets you deote more time to patient care, ss time to fussing with elecodes.

Infant System

Infants are special. So is American's Infant Electrode system: It puts a premium on comfort and reliable ECG or apnea monitoring.

Despite its small size and unusually mild gel, the silver/silver chloride Infant Electrode delivers up to 72 hours of the same high performance as American's adult Long Term Electrode.

The low profile leadwire connector fastens to the electrode without putting pressure on the infant.

Like all the other systems from American, the Infant Electrode and leadwire permit standardization of electrode connections throughout the hospital. You can enjoy the benefits of a system designed solely for monitoring infants with your present ECG equipment.

O.R. Electrode

This system answers the special needs of short term monitoring in operating and recovery rooms, or wherever there's a need for high performance on a short term basis.

American's O. R. Electrode delivers a strong signal and immediate base line stability.

Best of all, this advanced electrode is fully compatible with your present monitoring equipment, regardless of manufacturer or model. With the appropriate American leadwire and cable, the electrodes used for monitoring in the O.R. can be left on the patient for monitoring in the recovery room.

Clinical Trial

There's an American ECG electrode system ideally suited to your particular monitoring requirements.

Please contact your American Hospital Supply or NDM Representative and ask for:

- A complete demonstration of an American electrode system.
- A no obligation clinical trial. American will supply electrodes, leadwires and cables to adapt to your present monitoring units during the trial period.
- A total inservice for your staff.
- Information about our nationwide technical support program.

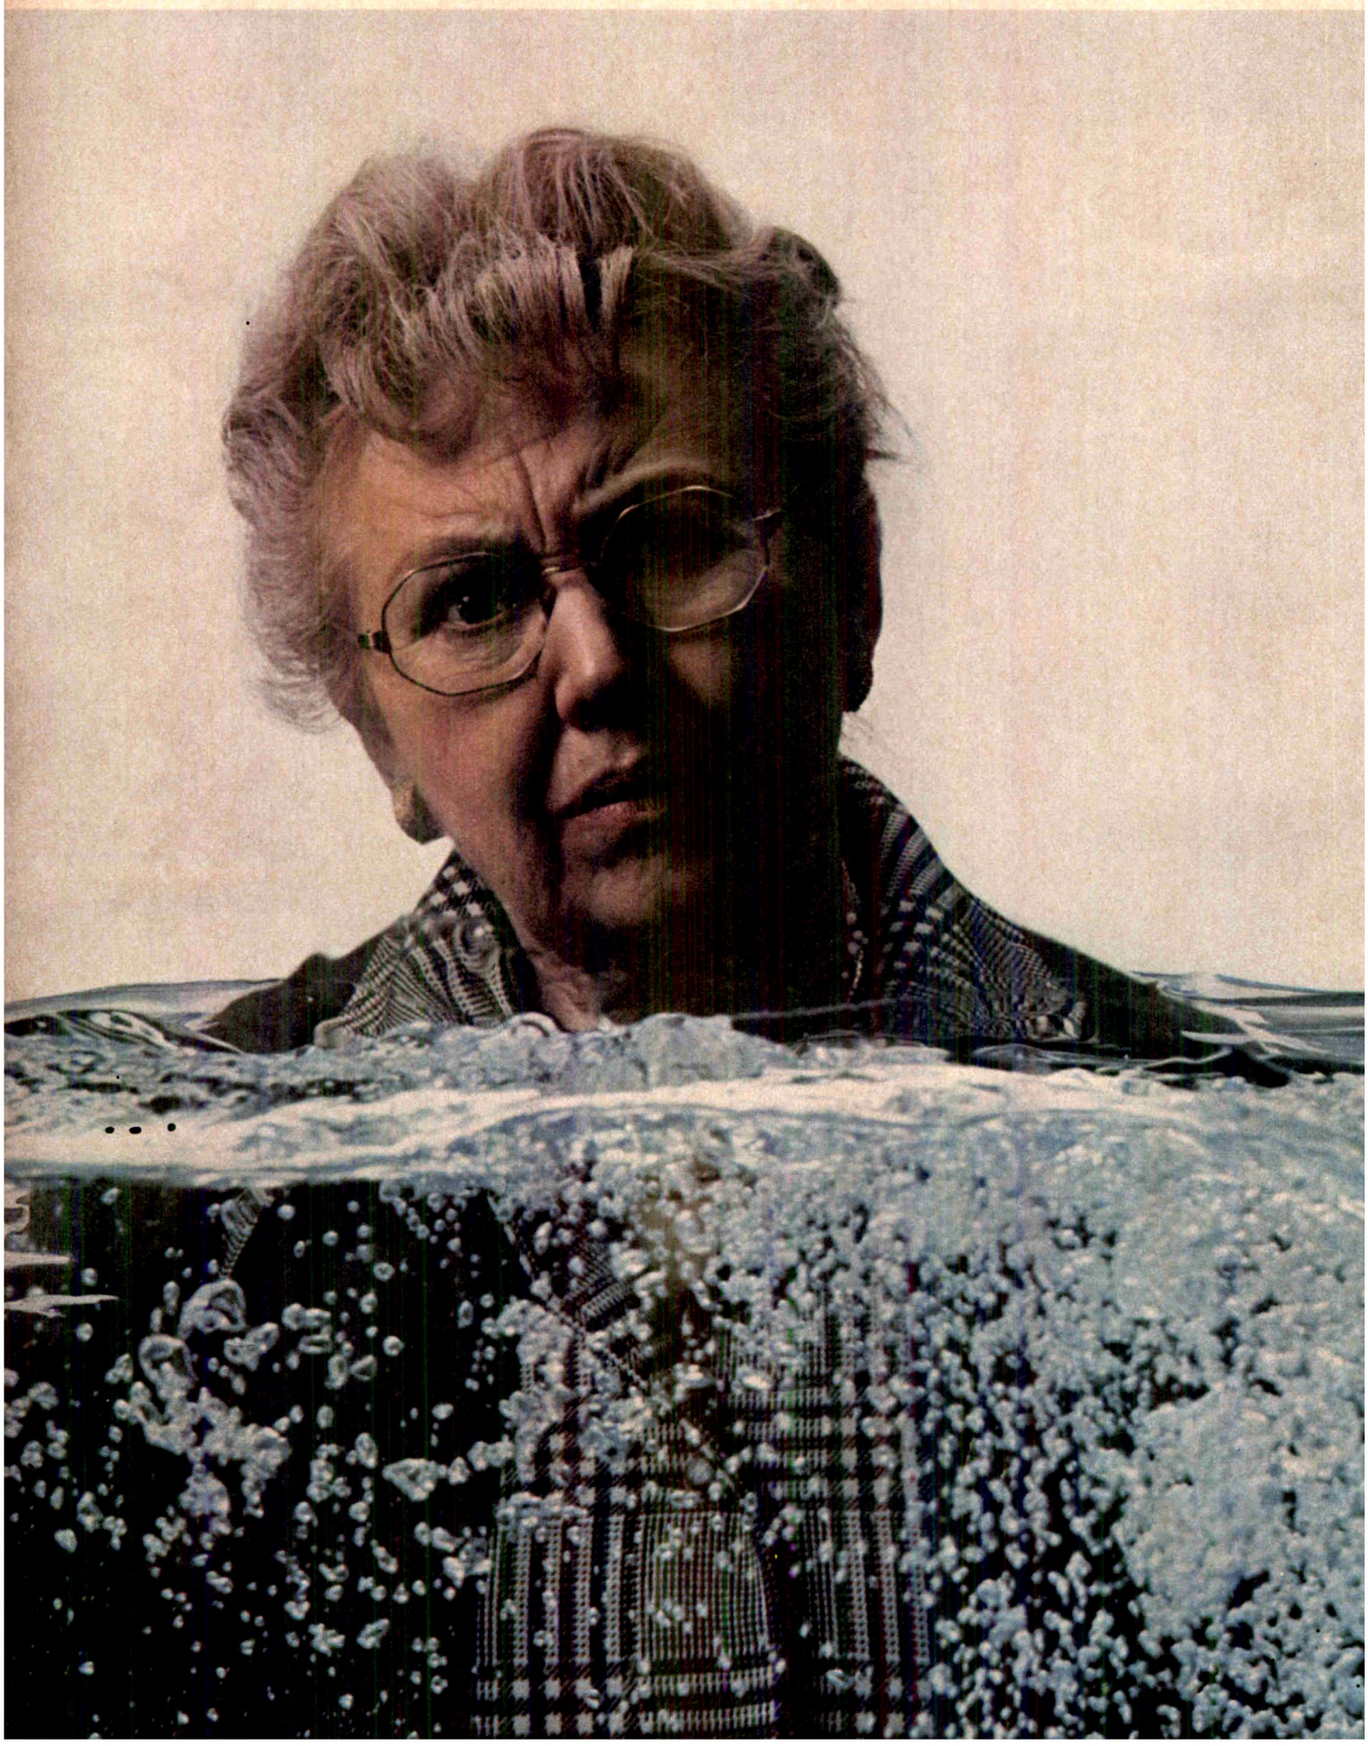
WHEN YOUR DIGITALIZED PATIENT NEEDS A DIURETIC



SHE NEEDS DYAZIDE®

RELIEVES EDEMA*

and maintains diuretic efficacy throughout therapy, regardless of aldosterone level

CONSERVES NATURAL POTASSIUM STORES

to reduce the risk of hypokalemia and its symptoms: malaise, fatigue and muscle cramps

REDUCES THE RISK OF DIGITALIS INTOXICATION

due to potassium depletion. Potassium depletion sensitizes the myocardium to the toxic effects of digitalis and reduces its inotropic effect.

The Dyrenium (triamterene, SK&F) component of 'Dyazide' conserves potassium. Therefore, dietary potassium supplements or potassium salts should not be used with 'Dyazide' unless hypokalemia develops or dietary intake of potassium is markedly impaired.

'Dyazide' can occasionally cause hyperkalemia. Accordingly, serum potassium and BUN should be checked during therapy, particularly in patients with suspected or confirmed renal insufficiency (e.g., elderly or diabetic patients).

If hyperkalemia develops, 'Dyazide' should be withdrawn and a thiazide alone substituted.

Use 'Dyazide' with caution during pregnancy or in women who might bear children. Its potential benefits should be weighed against possible hazards to the fetus.

*See next page for indications and brief prescribing information.

Trademark

DYAZIDE®

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

MEETS THE HEARTFELT NEED FOR POTASSIUM CONSERVATION

Trademark

DYAZIDE®

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

MEETS THE HEARTFELT NEEDS OF THE DIGITALIZED PATIENT

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications: Edema associated with congestive heart failure, cirrhosis of the liver, the nephrotic syndrome; steroid-induced and idiopathic edema; edema resistant to other diuretic therapy. Also, mild to moderate hypertension.

Contraindications: Pre-existing elevated serum potassium. Hypersensitivity to either component. Continued use in progressive renal or hepatic dysfunction or developing hyperkalemia.

Warnings: Do not use dietary potassium supplements or potassium salts unless hypokalemia develops or dietary potassium intake is markedly impaired. Enteric-coated potassium salts may cause small bowel stenosis with or without ulceration. Hyperkalemia (> 5.4 mEq/L) has been reported in 4% of patients under 60 years, in 12% of patients over 60 years, and in less than 8% of patients overall. Rarely, cases have been associated with cardiac irregularities. Accordingly, **check serum potassium during therapy, particularly in patients with suspected or confirmed renal insufficiency (e.g., elderly or diabetics). If hyperkalemia develops, substitute a thiazide alone. If spironolactone is used concomitantly with 'Dyazide', check serum potassium frequently**—both can cause potassium retention and sometimes hyperkalemia. Two deaths have been reported in patients on such combined therapy (in one, recommended dosage was exceeded; in the other, serum electrolytes were not properly monitored). Observe patients on 'Dyazide' regularly for possible blood dyscrasias, liver damage or other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving Dyrenium (triamterene, SK&F). Rarely, leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia have been reported with the thiazides. Watch for signs of impending coma in acutely ill cirrhotics. Thiazides are reported to cross the placental barrier and appear in breast milk. This may result in fetal or neonatal hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism and possibly other adverse reactions that have occurred in the adult. When used during pregnancy or in women who might bear children, weigh potential benefits against possible hazards to fetus.

Precautions: Do periodic serum electrolyte and BUN determinations. Do periodic hematologic studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in postsympathectomy patients. The following may occur: hyperuricemia and gout, reversible nitrogen retention, descreasing alkali reserve with possible metabolic acidosis, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), digitalis intoxication (in hypokalemia). Use cautiously in surgical patients. Concomitant use with antihypertensive agents may result in an additive hypotensive effect.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis; rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting (may indicate electrolyte imbalance), diarrhea, constipation, other gastrointestinal disturbances. Rarely, necrotizing vasculitis, paresthesias, icterus, pancreatitis, and xanthopsia have occurred with thiazides alone.

Supplied: Bottles and Single Unit Packages of 100 capsules.

819 Hemodynamic Effects of Noninvasive Systolic Unloading (Nitroprusside) and Diastolic Augmentation (External Counterpulsation) in Patients with Acute Myocardial Infarction

WILLIAM W. PARMLEY, KANU CHATTERJEE, YZHAR CHARUZI and H. J. C. SWAN

This study demonstrates the feasibility of combining noninvasive external counterpulsation and systolic unloading with infusion of nitroprusside to produce hemodynamic improvement in patients with acute myocardial infarction. The results of this combined therapy were better than those of either treatment alone in that counterpulsation reversed the decrease in diastolic blood pressure produced by nitroprusside and further increased the cardiac index.

826 Prognostic Indexes in Acute Myocardial Infarction Complicated by Shock

ABDELMONEM A. AFIFI, POTTER C. CHANG, VINNIE Y. LIU, PROTASIO L. da LUZ, MAX HARRY WEIL and HERBERT SHUBIN

Arterial blood lactate was the most reliable variable individually and in combination with other variables in assessing prognosis in 29 patients with acute myocardial infarction and shock. Blood flow measurements were more reliable than blood pressure measurements. Prognostic indexes like those discussed in this article provide an objective assessment of the severity of the patient's illness and his response to treatment.

833 Mechanism and Significance of Widened QRS Complexes During Complete Atrioventricular Block in Acute Inferior Myocardial Infarction

K. I. LIE, HEIN J. WELLONS, REINIER M. SCHUILENBURG and DIRK DURRER

Widened QRS complexes with a left bundle branch block configuration in patients with acute inferior wall myocardial infarction may be due to an atrioventricular (A–V) junctional escape rhythm with phase 4 left bundle branch block. Alternatively, in association with a right bundle branch block configuration they may represent a ventricular or fascicular escape rhythm. Widened QRS complexes during complete A–V block in acute inferior myocardial infarction have no prognostic significance.

840 Platelet Survival in Patients with Prosthetic Heart Vaves

R. KENNETH STUART, JOHN W. McDONALD, SURAJ P. AHUJA and JOHN C. COLES

These chromium-51 platelet survival studies in 20 patients with a prosthetic heart valve suggest that reduced platelet survival time was a result of damage to the prosthesis rather than of thrombus formation on the prosthesis. Only 1 of 10 patients with a prosthetic mitral valve and 4 of 10 patients with an aortic prosthesis had a significantly shortened platelet survival time.

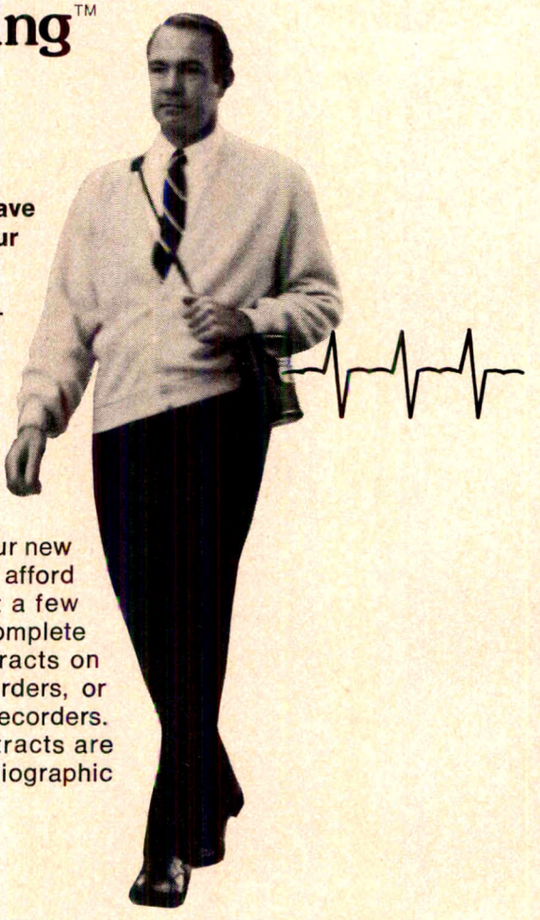
NOW AVAILABLE FROM AVIONICS...

Complete Service Contracts on Holter Monitoring™ Systems!



For as little as $66.50 per year you can have a full Service and Maintenance Contract on our 24-hour Models 400 or 425 Holter Monitors!

When you buy your Holter Monitor™ and Electrocardioscanner®, you are getting the know-how and back-up of the company that pioneered and established Dynamic Electrocardiography®, along with the availability of 15 sales and service centers throughout the United States and Canada, and in 47 countries abroad.

But now, something new has been added. Our new Series AA recorders are so reliable we can afford to make you a remarkable offer. For just a few dollars per year, you can now purchase complete service and preventive maintenance contracts on our new two pound 385/435 12-hour recorders, or our three pound Model 400/425 24-hour recorders. Service and Preventive Maintenance Contracts are available on all new Dynamic Electrocardiographic Systems and Exercise Stress Test Systems.

EXPERIMENTAL STUDIES

845 Encephalogenic Cardiomyopathy After Stimulation of the Brain Stem in Monkeys

HSING I. CHEN, SHIH CHIEN SUN, CHOK YUNG CHAI, SHIH LIANG KAU and CHIEN KOU

Repeated electrical stimulation of the hypothalamus, pons and medulla in monkeys produced an increase in arterial blood pressure, cardiac arrhythmias, S–T or T wave changes in the electrocardiogram and ultrastructural damage to the myocardium. The myocardial lesions are attributed to activation of the sympathetic mechanism in the brain stem.

853 Reflex Inhibitory Effects of Vagal Afferents in Experimental Myocardial Infarction

PAUL KEZDI, R. KARL KORDENAT and SARDA N. MISRA

After injection of mercury into the circumflex coronary artery of closed chest anesthetized dogs not only did cardiac output, mean blood pressure and aortic nerve activity decrease as expected, but also postganglionic sympathetic nerve activity decreased unexpectedly, probably because of a powerful cardiac vagal afferent reflex. Cutting or blocking the vagus nerves immediately increased sympathetic nerve activity and then cardiac output, mean systemic blood pressure and aortic nerve activity in these animals.

861 Accumulation of Gallium-67 in Regions of Acute Myocardial Infarction

ROBERT J. KRAMER, ROBERT E. GOLDSTEIN, JOHN W. HIRSHFELD, Jr., WILLIAM C. ROBERTS, GERALD S. JOHNSTON and STEPHEN E. EPSTEIN

Radionuclide gallium-67 injected intravenously in eight dogs after ligation of the left anterior descending artery was found to accumulate preferentially in regions of visible infarction in five hearts removed 24 hours later. Additional data in this study suggest ^{67}Ga localization discriminates infarcted from normal or only transiently ischemic yocardium. ^{67}Ga scanning may prove particularly useful in the imaging of acute myocardial infarction in man.

868 Dimensional Changes of the Left Ventricle During Acute Pulmonary Arterial Hypertension in Dogs

EDWARD W. STOOL, CHARLES B. MULLINS, STEPHEN J. LESHIN and JERE H. MITCHELL

In these closed chest experiments in eight dogs progressive increases of 10 mm Hg in mean pulmonary arterial pressure increased right ventricular volume. Left ventricular volume began to decrease significantly at a mean pulmonary arterial pressure of 30 mm Hg, and was associated with a disproportionate reduction in left ventricular septal-lateral axis. During acute pulmonary hypertension progressive dilatation of the right ventricle caused a distinctive change in the left ventricular shape, suggesting septal bulging capable of impairing left ventricular function.

876 Ventricular Conduction Delay and Asystole During Systemic Hyperkalemia

PHILIP O. ETTINGER, TIMOTHY J. REGAN, HENRY A. OLDEWURTEL and MOHAMMAD I. KHAN

Systemic hyperkalemia induced in 30 intact dogs initiated A–V junctional delay and block followed by accelerated junctional pacemakers and ventricular conduction delays leading to unusual arrhythmias. Terminal Purkinje or Purkinje muscle block was the dominant mechanism of arrest with conduction through the ventricular specialized conduction system continuing at a regular rate even after asystole. In view of the absence of ischemia, conduction delays appear to be responsible for the abnormal ventricular function.

Beat after beat...day after day

CARDIOQUIN tablets

(quinidine polygalacturonate)

To convert...to MAINTAIN normal sinus rhythm

After conversion of cardiac arrhythmias—whether with CARDIOQUIN Tablets or some other current method—only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required in most cases to maintain normal sinus rhythm.

Well-tolerated, CARDIOQUIN Tablets are particularly suited for maintenance therapy, since the polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*Aviado, D. M., *Krantz and Carr's Pharmacologic Principles of Medical Practice*, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heartblock; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 50.

METHODS

887 Permanent Pervenous Transseptal Atrial Pacing. Canine Experiments and a Clinical Case

JOHN A. UDALL

Using a Ross needle to carry a 10 mm T-shaped electrode tip across the atrial septum, these investigators demonstrated the successful application and safety of permanent pervenous transseptal atrial pacing in a series of 10 dogs and finally in a 78 year old man suffering from carotid sinus syncope. The dog hearts were paced successfully for 3 to 12 months with average thresholds of 6 ma, and the patient became asymptomatic.

PEDIATRIC CARDIOLOGY

892 Evaluation of Patients with Pulmonary Atresia and Intact Ventricular Septum by Double Catheter Technique

ROBERT M. FREEDOM, ROBERT I. WHITE, Jr., CHARLES S. HO, ROBERT L. GINGELL, RICHARD E. HAWKER and RICHARD D. ROWE

This double catheter technique permitted simultaneous opacification of the pulmonary artery by way of the ductus arteriosus or systemic to pulmonary arterial anastomosis by one catheter and the right ventricle by the second catheter in five patients with pulmonary atresia. This technique is also applicable to patients with ventricular septal defect and acquired or congenital pulmonary atresia who have had palliative shunts, and to patients with complex transpositions and pulmonary atresia. Accurate definition of the type of pulmonary atresia by this technique should improve surgical results in these difficult cases.

896 Echocardiographic Assessment of Cardiac Malposition

RICHARD A. MEYER, DAVID C. SCHWARTZ, WESLEY COVITZ and SAMUEL KAPAN

Echocardiographic studies in 15 children with cardiac malposition demonstrate that this noninvasive technique and the knowledge of atrial situs determined from plain chest roentgenograms can define accurately important anatomic relations before cardiac catheterization and angiography.

HISTORICAL MILESTONES

904 Experimental Mitral Insufficiency (Bettelheim and Kauders)

SAUL JARCHO

Although performed at the end of the last century chiefly for clinical and physiologic purposes, these dog experiments on the production of mitral insufficiency clearly constitute a noteworthy historical introduction to this century's great advances in the surgical repair of heart valves in human beings.

CASE REPORTS

908 Tachycardia-Dependent and Bradycardia-Dependent Mobitz Type II Atrioventricular Block Within the Bundle of His

MICHAEL A. GOODFRIEND and S. SERGE BAROLD

After excessive alcohol intake interesting rate-related transient second and third degree A–V block (Mobitz type II) with a normal QRS complex was noted in a 27 year old man. Electrograms demonstrated the lesion within the proximal portion of the His bundle.

914 Mitral and Tricuspid Lesions Associated with Polypoid Atrial Tumors, Including Myxoma

JOHN B. CARTER, RALPH CRAMER, Jr. and JESSE E. EDWARDS

Lesions of the mitral valve in seven of nine patients with left atrial tumors and of the tricuspid leaflets in two patients with right atrial myxoma are considered responses to the effects of friction by the tumor upon the surfaces involved.

920 Caseating Granulomas of the Heart

T. STERLING CLAIBORNE

Calcified masses within the myocardium of this 49 year old woman turned out on autopsy to be caseating granulomas, presumably due to tuberculosis, a most rare condition in this era of declining frequency of acid-fast infections.

924 Emergency Thrombectomy for Acute Coronary Bypass Graft Occlusion

J. EDWARD OKIES and RICHARD P. ANDERSON

Two patients with symptomatic occlusion of a bypass graft during early convalescence were successfully treated by emergency operative thrombectomy and reanastomosis of the grafts. Coronary angiography to locate occluded grafts is indicated when signs and symptoms of myocardial ischemia reappear in the immediate postoperative period.

Wouldn't it be
nice if nitroglycerin
alone were the
answer?
For the angina* patient who
may need more than nitroglycerin:
Peritrate® SA
Sustained Action
(pentaerythritol tetranitrate) 80 mg
Prolonged prophylaxis with minimum side effects
*The drug has been evaluated as possibly effective for this indication. See brief summary

Peritrate® SA

Sustained Action
(pentaerythritol tetranitrate) 80 mg

CAUTION: Federal law prohibits dispensing without prescription.

Each tablet of Peritrate SA Sustained Action contains: pentaerythritol tetranitrate 80 mg (20 mg in immediate release layer and 60 mg in sustained release base). Peritrate® (pentaerythritol tetranitrate) is a nitric acid ester of a tetrahydric alcohol (pentaerythritol).

Indications: Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: Peritrate (pentaerythritol tetranitrate), is indicated for the relief of angina pectoris (pain associated with coronary artery disease). It is not intended to abort the acute anginal episode but it is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg is contraindicated in patients who have a history of sensitivity to the drug.

Warning: Data supporting the use of Peritrate (pentaerythritol tetranitrate) during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance to this drug, and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Side effects reported to date have been predominantly related to rash (which requires discontinuation of medication) and headache and gastrointestinal distress, which are usually mild and transient with continuation of medication. In some cases severe persistent headaches may occur.

In addition, the following adverse reactions to nitrates such as pentaerythritol tetranitrate have been reported in the literature:

(a) Cutaneous vasodilatation with flushing.
(b) Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop.
(c) An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur, even with the usual therapeutic doses. Alcohol may enhance this effect.

Dosage: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg (b.i.d. on an empty stomach), 1 tablet immediately on arising and 1 tablet 12 hours later.

Supplied: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg, double layer, biconvex, dark green/light green tablets in bottles of 100 and 1000.

Additional Dosage Forms: Peritrate 20 mg–light green, scored tablets; Peritrate 10 mg–light green, unscored tablets. Bottles of 100 and 1000. Full information is available on request.

New Respiratory Gas Analyzer and Stress Test Monitor...

Now, for the first time, totally automatic, minute-by-minute update of respiratory functions during physical stress testing – plus continuous ECG monitoring – all in one compact system!

A. MODEL 800 RESPIRATORY GAS ANALYZER

- All digital data continuously displayed and updated each minute
- Expired volume up to 199.9 liters per minute B.T.P.S.
- Oxygen uptake up to 9.99 liters per minute S.T.P.D.
- Oxygen uptake per kilogram body weight per minute up to 99.9 milliliters
- CO_2 in liters per minute, and RQ
- Total heart beats per minute
- Elapsed-time clock synchronizes complete system and provides digital display
- Digital outputs for printers and plotters

B. MODEL 2900 STRESS TEST MONITOR

- Large, two-channel oscilloscope displays ECG waveform
- Built-in digital heart rate meter numerically displays instantaneous or average heart rate
- Built-in ECG paperwriter meets AHA recommendations
- Optional automatic timer/programmer automatically controls paperwriter
- Optional S-T segment computer/display numerically displays S-T elevations and depressions

CORRECTION

The following changes, indicated in italics, should be made in the article by Dawson et al. in the April issue (Dawson JT, Hall RJ, Hallman GL, et al: Mortality in patients undergoing coronary artery bypass surgery after myocardial infarction. Am J Cardiol 33:483–486, 1974):

Page 483, last sentence: Electrocardiographic changes in *patients in Group 3* included development of Q waves in all but two patients.

Page 485, last line, column one: It is also apparent that early mortality in patients who undergo operation *31 to 60 days after* an acute myocardial infarction is no greater than in those who experience an infarction more than 2 months before operation.

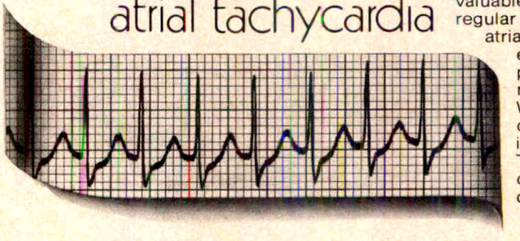
Page 496, line 3: The more severe complications, including shock and severe heart failure, were present only in patients operated on *less than 8 days* after infarction.

in the inner circle o
Inderal® stands ou

The place of INDERAL (propranolol hydrochloride) among the standard drugs for the treatment of disturbed cardiac rhythm has been frequently reaffirmed throughout seven years of clinical use. In fact, after withdrawal of digitalis, "...it may be the treatment of choice for digitalis-induced arrhythmias, provided hypokalemia is not present."[1] It has been widely used in selected supraventricular arrhythmias that have proved resistant to digitalis and in tachyarrhythmias precipitated by exercise, emotional stress, or undesirable sympathetic stimulation; and it is also effective in controlling supraventricular tachyarrhythmias related to the Wolff-Parkinson-White syndrome.[2]

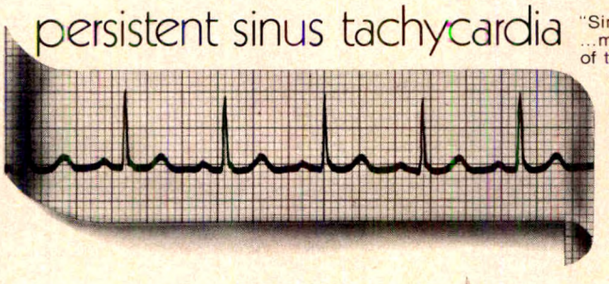
INDERAL protects the heart from undesirable catecholamine stimulation through its beta blocking action. Propranolol occupies the beta-receptor sites, making them unavailable to the beta-adrenergic stimulating effects of catecholamines. INDERAL is the first beta-adrenergic blocking agent in clinical cardiologic use.

paroxysmal atrial tachycardia



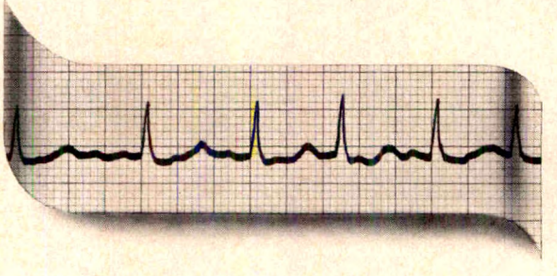
"In paroxysmal atrial tachycardia, the d slows the ventricular rate, and als valuable in restoring the heart regular sinus rhythm."[3] "Paroxys atrial tachycardia induced by ercise...has uniformly b prevented by propranolol," results with INDERAL in Wolff-Parkinson-White s drome"...have been favor in all but a few patients repo This condition appears to one of the more definite i cations for propranolol."[4]

persistent sinus tachycardia



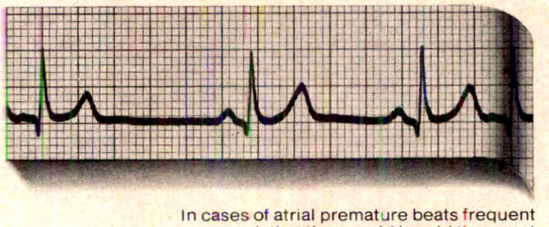
"Sinus tachycardia induced by stress ...may be inappropriate to the needs of the patient and, in fact, may be causing symptoms of itself. If the clinical situation does not suggest a needed compensatory sinus tachycardia and the heart rate is indeed inappropriate, treatment with propranolol has been successful."[4]

tachycardias and arrhythmias due to thyrotoxicosis



Although propranolol may accomplish only the reduction of the heart rate in hyperthyroidism, it has proved useful for this purpose. "Sinus tachycardia in hyperthyroidism which causes symptoms may be relieved by the administration of propranolol before definitive therapy....The author has observed that atrial fibrillation complicating hyperthyroidism was easily terminated using modest doses of propranolol."[4]

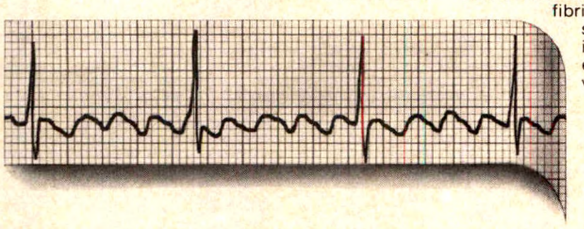
persistent atrial extrasystoles



In cases of atrial premature beats frequent enough that they could herald the onset of atrial fibrillation, it has been recommended that propranolol be used after other measures have failed to control the beats.[5]

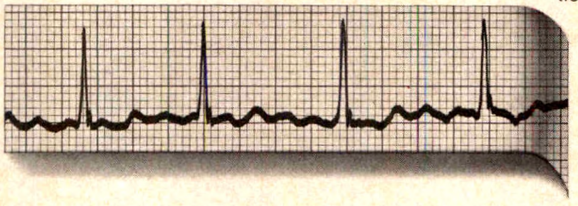
antiarrhythmia agents for supraventricular arrhythmias

atrial flutter



"In the presence of atrial flutter, ventricular rate is often difficult to control, and, as with an atrial fibrillation, propranolol hydrochloride should be added when the flutter is not controlled by digitalis, especially in the presence of mitral valve disease."[6]

atrial fibrillation



"One salutary effect of propranolol is slowing of the ventricular rate in atrial flutter and fibrillation."[4] In a review of the literature, it was noted that most patients with fibrillation not controlled by digitalis alone experienced slowing of the ventricular rate after administration of propranolol and a few reverted to sinus rhythm.[7]

---

and for tachyarrhythmias of digitalis intoxication

"Propranolol is very effective in treating arrhythmias caused by digitalis excess. Its use in this setting may be limited by the presence of significant congestive heart failure or heart block, both of which can be potentiated by propranolol. However, if given in small doses with careful monitoring, it is often of great value in the treatment of digitalis toxicity."[5]

Inderal®

Brand of propranolol hydrochloride

helps prevent or control catecholamine-induced cardiac arrhythmias

Ayerst

AYERST LABORATORIES
New York, N.Y. 10017

BETA-BLOCKADE/**INDERAL**®
(propranolol hydrochloride)

(See last page of advertisement for prescribing information.)

BRIEF SUMMARY
(For full prescribing information, see package circular.)

Inderal®

Brand of
propranolol hydrochloride

A beta-adrenergic blocking agent

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

INDICATIONS:

Cardiac Arrhythmias

1.) Supraventricular arrhythmias

a) Paroxysmal atrial tachycardias, particularly those arrhythmias induced by catecholamines or digitalis or associated with the Wolff-Parkinson-White syndrome. (See W-P-W under WARNINGS.)

b) Persistent sinus tachycardia which is non-compensatory and impairs the well-being of the patient.

c) Tachycardias and arrhythmias due to thyrotoxicosis when causing distress or increased hazard and when immediate effect is necessary as adjunctive, short term (2-4 weeks) therapy.
May be used with, but not in place of, specific therapy. (See Thyrotoxicosis under WARNINGS.)

d) Persistent atrial extrasystoles which impair the well-being of the patient and do not respond to conventional measures.

e) Atrial flutter and fibrillation when ventricular rate cannot be controlled by digitalis alone, or when digitalis is contraindicated.

2.) Ventricular tachycardias
Ventricular arrhythmias do not respond to propranolol as predictably as do the supraventricular arrhythmias.

a) Ventricular tachycardias
With the exception of those induced by catecholamines or digitalis, INDERAL is not the drug of first choice. In critical situations when cardioversion technics or other drugs are not indicated or are not effective, INDERAL may be considered. If, after consideration of the risks involved, INDERAL is used, it should be given intravenously in low dosage and very slowly. (See DOSAGE AND ADMINISTRATION.) *Care in the administration of* INDERAL *with constant electrocardiographic monitoring is essential as the failing heart requires some sympathetic drive for maintenance of myocardial tone.*

b) Persistent premature ventricular extrasystoles which do not respond to conventional measures and impair the well-being of the patient.

3.) Tachyarrhythmias of digitalis intoxication
If digitalis-induced tachyarrhythmias persist following discontinuance of digitalis and correction of electrolyte abnormalities, they are usually reversible with *oral* INDERAL. Severe bradycardia may occur. (See OVERDOSAGE OR EXAGGERATED RESPONSE.) Intravenous propranolol hydrochloride is reserved for life-threatening arrhythmias. Temporary maintenance with oral therapy may be indicated. (See DOSAGE AND ADMINISTRATION.)

4.) Resistant tachyarrhythmias due to excessive catecholamine action during anesthesia.
Tachyarrhythmias due to excessive catecholamine action during anesthesia may sometimes arise because of release of endogenous catecholamines or administration of catecholamines. When usual measures fail in such arrhythmias, INDERAL may be given intravenously to abolish them. All general inhalation anesthetics produce some degree of myocardial depression. Therefore, when INDERAL is used to treat arrhythmias during anesthesia, it should be used with extreme caution and constant ECG and central venous pressure monitoring. (See WARNINGS.)

Hypertrophic Subaortic Stenosis
INDERAL is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL also improves exercise performance. The effectiveness of INDERAL in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta receptor stimulation. Clinical improvement may be temporary.

Pheochromocytoma
After primary treatment with an alpha-adrenergic blocking agent has been instituted, INDERAL may be useful as *adjunctive* therapy if the control of tachycardia becomes necessary before or during surgery.

It is hazardous to use INDERAL unless alpha-adrenergic blocking drugs are already in use, since this would predispose to serious blood pressure elevation. Blocking only the peripheral dilator (beta) action of epinephrine leaves its constrictor (alpha) action unopposed.

In the event of hemorrhage or shock, there is a disadvantage in having both beta and alpha blockade since the combination prevents the increase in heart rate and peripheral vasoconstriction needed to maintain blood pressure.

With inoperable or metastatic pheochromocytoma, INDERAL may be useful as an adjunct to the management of symptoms due to excessive beta receptor stimulation.

CONTRAINDICATIONS: INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS: CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.* that of supporting the strength of myocardial contractions). However, the inotropic action of digitalis may be reduced by INDERAL's opposite inotropic effect. The effect of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized, and the response observed closely: (a) if cardiac failure continues, INDERAL therapy must be immediately withdrawn; (b) if tachyarrhythmia is being controlled, patients should be maintained on combined dosage and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg. propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.* isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.* CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. Especially important with labile diabetics.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit.

PRECAUTIONS: Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

When discontinuance of chronically administered INDERAL is planned, the dosage should be gradually reduced over a period of several weeks and the patient should continue to be carefully monitored. There have been reports of myocardial infarction occurring in angina pectoris patients following *abrupt* discontinuation of INDERAL therapy.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS: *Cardiovascular:* bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura.

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress

Respiratory: bronchospasm

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura

Miscellaneous: reversible alopecia

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase

DOSAGE AND ADMINISTRATION: The oral route of administration is preferred.

ORAL

ARRHYTHMIAS—10-30 mg. three or four times daily, before meals and at bedtime.

HYPERTROPHIC SUBAORTIC STENOSIS—20-40 mg. three or four times daily, before meals and at bedtime.

PHEOCHROMOCYTOMA—*Preoperatively*—60 mg. daily in divided doses for three days prior to surgery, concomitantly with an alpha-adrenergic blocking agent.

—*Management of inoperable tumor*—30 mg. daily in divided doses.

PEDIATRIC DOSAGE

At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

INTRAVENOUS

Intravenous administration is reserved for life-threatening arrhythmias or those occurring under anesthesia. The usual dose is from 1 to 3 mg. administered under careful monitoring, *e.g.* electrocardiographic, central venous pressure. The rate of administration should not exceed 1 mg. (1 cc.) per minute to diminish the possibility of lowering blood pressure and causing cardiac standstill. Sufficient time should be allowed for the drug to reach the site of action even when a slow circulation is present. If necessary, a second dose may be given after two minutes. Thereafter, additional drug should not be given in less than four hours. Additional INDERAL should not be given when the desired alteration in rate and/or rhythm is achieved.

Transference to oral therapy should be made as soon as possible.

OVERDOSAGE OR EXAGGERATED RESPONSE: IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED: BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg.): IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS

HYPOTENSION—VASOPRESSORS, *e.g.* LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE.)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE.

HOW SUPPLIED: INDERAL (propranolol hydrochloride) TABLETS No. 461—Each tablet contains 10 mg. of propranolol hydrochloride, in bottles of 100 and 1,000.

No. 464—Each tablet contains 40 mg. of propranolol hydrochloride, in bottles of 100 and 1,000.

INJECTABLE No. 3265—Each cc. contains 1 mg. of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 cc. ampuls in boxes of 10.

On Reliability and a Pound of Flesh

The life's blood of an electrocardiograph is the chart that flows through it.

Assurance that the recording is totally reliable depends, in part, on the quality of the chart itself.

Charts, as provided by the instrument maker, afford this assurance to a maxima ... because they are designed as an integral part of the instrument.

Charts, as provided by others, are imitations at best. They may save a few pennies, but not without risk of shedding a "drop of reliability".

This message was prepared in the interest of better instrument performance by ...

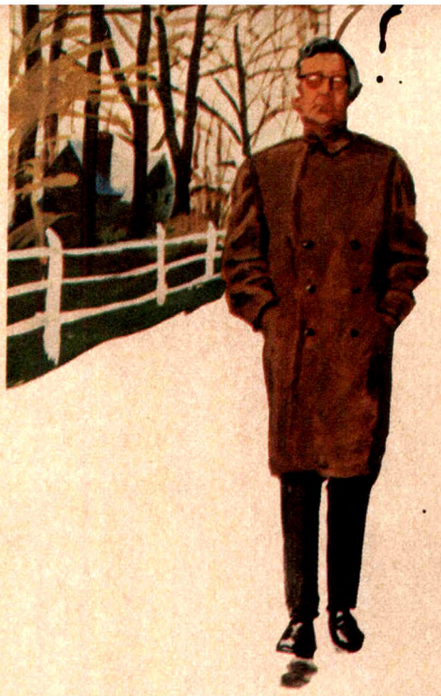
If psychic tension interferes with cardiac rehabilitation, here's how Valium® can help.
(diazepam)

During hospitalization, Valium (diazepam) can relieve psychic tension that can disrup bed rest and interfere with the rehabilitation program.

After the MI patient is stabilized, a certain amount of psychic tension is to be expected. Your reassurance, counseling and enlistment of family support can often minimize its effects. However, in some instances, the patient's thoughts may dwell constantly on his condition and how it will affect his life, thus producing excessive psychic tension that ma present special problems. He may feel overwhelmed and be so burdened by these tensions that he is unable to rest and unable or unwilling to begin a program of rehabilitatior Under these circumstances, Valium® (diazepam) can often be a beneficial adjunct.

Valium can calm the cardiac patient and help reduce his psychic tension to appropri ate levels. Valium is used with most classes of primary medications such as cardiac glycosides, diuretics, vasodilators, anticoagulants, anticholinergics and antacids. Careful consideration should be given to the pharmacology of agents used with Valium, particularly those which may potentiate its action.



During convalescence at home, Valium (diazepam) can reduce excessive anxiety that may hinder participation in active rehabilitation.

Your counseling and the family's support do much to control the anxieties that may interfere with this stage of convalescence—a time when you may wish to encourage a gradual increase in activity. But in some patients, excessive anxiety may retard general progress. For them, Valium can be beneficial during the post-hospital transition to full ambulation. And, because the convalescent cardiac patient may be particularly prone to excessive tension and anxiety at bedtime, the addition of an *h.s.* dose of Valium to the *b.i.d.* or *t.i.d.* schedule can reduce these symptoms and thus may encourage sleep. Therapy with Valium should be discontinued when symptoms have been reduced to tolerable levels.

What an informed cardiac patient should know about Valium therapy.

The cardiac patient should know that he can generally expect Valium to help relax and calm him so that he won't feel so overwhelmed by his tension and anxiety. An explanation of the importance of the dosage regimen you prescribe may go a long way to ensure his cooperation. As with all CNS-acting agents, the patient taking Valium should be cautioned against driving or operating dangerous machinery.

Valium® (diazepam)

2-mg, 5-mg, 10-mg tablets can relieve the cardiac patient's undue psychic tension

ROCHE

For a summary of product information, see the following page.

Valium® (diazepam)
2-mg, 5-mg, 10-mg tablets
can relieve the cardiac patient's undue psychic tension

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology, spasticity caused by upper motor neuron disorders, athetosis, stiff-man syndrome, convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg; bottles of 100 and 500. All strengths also available in Tel-E-Dose® packages of 100.

Now, when you turn on increased cardiac output, vital organ perfusion and renal flow . . .

. . . you don't have to turn on the high risk of undesirable effects.

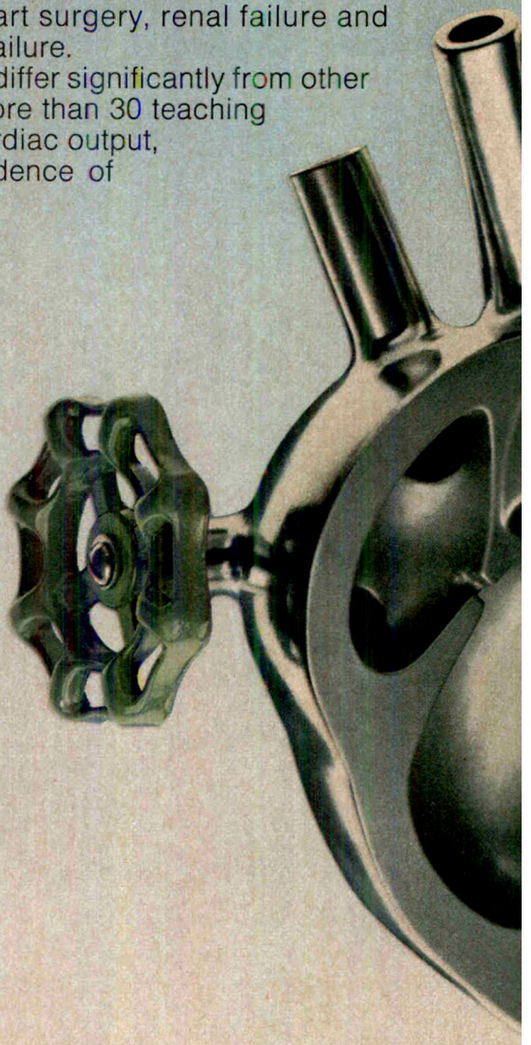
Introducing INTROPIN® (dopamine HCl)
for the correction of hemodynamic imbalances in the shock syndrome
due to: myocardial infarction, trauma, endotoxic septicemia,
open heart surgery, renal failure
and cardiac decompensation as in congestive failure.

Complete product information and a Clinical Reprint Order Form appear on the last two pages of this advertisement.

INTROPIN® (dopamine HCl) can increa
without the high r

Intropin is indicated for the correction of hemodynamic imbalances in the shock syndrome due to: myocardial infarction, open heart surgery, renal failure and chronic cardiac decompensation as in congestive failure.

The pharmacological actions of Intropin appear to differ significantly from other catecholamines. Over 6 years of clinical trials at more than 30 teaching hospitals have shown that Intropin can increase cardiac output, vital organ perfusion and renal flow with a low incidence of undesirable effects.



INTROPIN usually will:

increase perfusion to vital organs

Multiclinic trials have demonstrated that Intropin provides adequate perfusion of vital organs. This is based upon a number of clinical parameters including an increase in urine flow which appears to be one of the better diagnostic signs of increased vital organ perfusion.

At doses above those optimal for the individual patient, urine flow may decrease, necessitating reduction of dosage.

increase urine output

Intropin significantly increases urine flow. This is in contrast to most other sympathomimetic amines, which usually cause little or no significant increase in urine output.

This increased urine output is due to increases in glomerular filtration rate and renal blood flow and is accompanied by increased sodium excretion. Intropin may also increase urine flow in patients whose urine output is within normal limits and may promote diuresis usually with no decrease in osmolality.

increase cardiac output

Intropin acts predominantly on the beta receptors of the heart to substantially increase contractility, stroke volume and cardiac output, as confirmed by invasive technique.

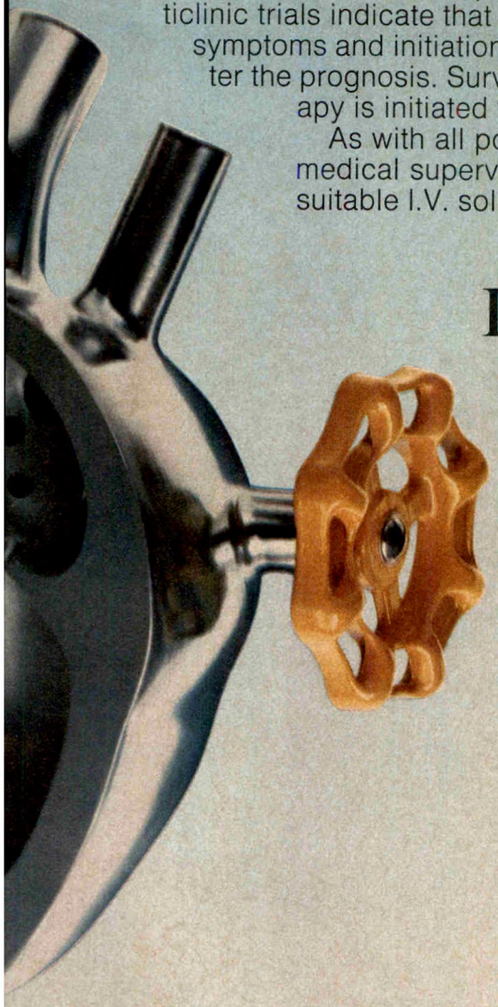
increase blood pressure

Hypotension due to inadequate cardiac output can be managed by administration of low to moderate doses of Intropin. Prognosis is better in patients whose blood pressure and urine flow have not undergone profound deterioration. Therefore, it is suggested that the physician administer Intropin as soon as a definite trend toward decreased systolic and diastolic pressure becomes evident.

rdiac output and vital organ perfusion undesirable effects.

Patients most likely to respond adequately to Intropin are those in whom urine flow, myocardial function and blood pressure have not undergone profound deterioration. Multiclinic trials indicate that the shorter the time interval between onset of signs and symptoms and initiation of therapy with volume correction and Intropin, the better the prognosis. Survival rates are considerably improved when Intropin therapy is initiated within 4 hours of onset of symptoms.

As with all potent drugs, Intropin must be administered under close medical supervision. It is administered only by I.V. drip after dilution in a suitable I.V. solution.



INTROPIN usually will not:

cause excessive myocardial oxygen consumption

Intropin produces less increase in myocardial oxygen consumption than isoproterenol. During administration of Intropin, the myocardial oxygen supply/demand ratio has usually remained stable. Intropin appears to meet additional myocardial oxygen requirements by increasing coronary flow.

substantially increase tachyarrhythmias

One investigator reported less than a 3% incidence of tachyarrhythmias in clinical trials in 270 patients. The tachyarrhythmias which occurred were easily managed.

increase total peripheral resistance

Administration of Intropin, at low and intermediate dosages, generally does not increase total peripheral vascular resistance. Blood flow to peripheral vascular beds may decrease while mesenteric flow increases.

Serious undesirable effects seldom occur.

In multiclinic studies, adverse reactions necessitated discontinuation of Intropin therapy in only 11 (2%) of 526 patients.

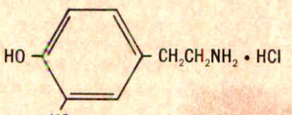
Additional product information and a Clinical Reprint Order Form appear on the following pages.

ARNAR-STONE LABORATORIES, INC.

INTROPIN® (dopamine HCl)

5 ml. AMPUL / FOR I.V. INJECTION

DESCRIPTION: INTROPIN (dopamine HCl) is 3,4-dihydroxyphenethylamine hydrochloride, a naturally-occurring biochemical catecholamine precursor of norepinephrine. The chemical structure is:



$C_8H_{11}NO_2 \cdot HCl$ Mol. Wt. 189.65

Dopamine hydrochloride is a white, odorless crystalline powder, freely soluble in water and soluble in alcohol. It is sensitive to light, alkalis, iron salts and oxidizing agents.

Each milliliter of sterile, pyrogen-free INTROPIN Injection contains 40 mg. of dopamine hydrochloride (equivalent to 32.96 mg. of dopamine base) in Water for Injection, USP, containing 1% sodium bisulfite as a preservative.

ACTIONS: INTROPIN exerts an inotropic effect on the myocardium resulting in an increased cardiac output. INTROPIN produces less increase in myocardial oxygen consumption than isoproterenol and its use is usually not associated with a tachyarrhythmia. Clinical studies indicate that INTROPIN usually increases systolic and pulse pressure with either no effect or a slight increase in diastolic pressure. Total peripheral resistance at low and intermediate therapeutic doses is usually unchanged. Blood flow to peripheral vascular beds may decrease while mesenteric flow increases. INTROPIN has also been reported to dilate the renal vasculature presumptively by activation of a "dopaminergic" receptor. This action is accompanied by increases in glomerular filtration rate, renal blood flow, and sodium excretion. An increase in urinary output produced by dopamine is usually not associated with a decrease in osmolality of the urine.

INDICATIONS: INTROPIN is indicated for the correction of hemodynamic imbalances present in the shock syndrome due to myocardial infarctions, trauma, endotoxic septicemia, open heart surgery, renal failure, and chronic cardiac decompensation as in congestive failure.

Where appropriate, restoration of blood volume with a suitable plasma expander or whole blood should be instituted or completed prior to administration of INTROPIN.

Patients most likely to respond adequately to INTROPIN are those in whom physiological parameters, such as urine flow, myocardial function and blood pressure, have not undergone profound deterioration. Multiclinic trials indicate that the shorter the time interval between onset of signs and symptoms and initiation of therapy with volume correction and INTROPIN, the better the prognosis.

Poor Perfusion of Vital Organs—Urine flow appears to be one of the better diagnostic signs by which adequacy of vital organ perfusion can be monitored. Nevertheless, the physician should also observe the patient for signs of reversal of confusion or comatose condition. Loss of pallor, increase in toe temperature, and/or adequacy of nail bed capillary filling may also be used as indices of adequate dosage. Clinical studies have shown that when INTROPIN is administered before urine flow has diminished to levels approximating 0.3 ml./minute, prognosis is more favorable. Nevertheless, in a number of oliguric or anuric patients, administration of INTROPIN has resulted in an increase in urine flow which in some cases reached normal levels. INTROPIN may also increase urine flow in patients whose output is within normal limits and thus may be of value in reducing the degree of pre-existing fluid accumulation. It should be noted that at doses above those optimal for the individual patient, urine flow may decrease, necessitating reduction of dosage. Concurrent administration of INTROPIN and diuretic agents may produce an additive or potentiating effect.

Low Cardiac Output—Increased cardiac output is related to INTROPIN's direct inotropic effect on the myocardium. Increased cardiac output at low or moderate doses appears to be related to a favorable prognosis. Increase in cardiac output has been associated with either static or decreased systemic vascular resistance (SVR). Static or decreased SVR associated with low or moderate increments in cardiac output is believed to be a reflection of differential effects on specific vascular beds with increased resistance in peripheral beds (e.g. femoral) and concomitant decreases in mesenteric and renal vascular beds. Redistribution of blood flow parallels these changes so that an increase in cardiac output is accompanied by an increase in mesenteric and renal blood flow. In many instances the renal fraction of the total cardiac output has been found to increase. Increase in cardiac output produced by INTROPIN is not associated with substantial decreases in systemic vascular resistance as may occur with isoproterenol.

Hypotension—Hypotension due to inadequate cardiac output can be managed by administration of low to moderate doses of INTROPIN, which have little effect on SVR. At high therapeutic doses, INTROPIN's alpha adrenergic activity becomes more prominent and thus may correct hypotension due to diminished SVR. As in the case of other circulatory decompensation states, prognosis is better in patients whose blood pressure and urine flow have not undergone profound deterioration. Therefore, it is suggested that the physician administer INTROPIN as soon as a definite trend toward decreased systolic and diastolic pressure becomes evident.

CONTRAINDICATIONS: INTROPIN should not be used in patients with pheochromocytoma.

WARNINGS: INTROPIN should not be administered in the presence of uncorrected tachyarrhythmias or ventricular fibrillation.

Do **NOT** add INTROPIN to any alkaline diluent solution, since the drug is inactivated in alkaline solution.

Patients who have been treated with monamine oxidase (MAO) inhibitors prior to the administration of INTROPIN will require substantially reduced dosage. Dopamine is metabolized by MAO, and inhibition of this enzyme prolongs and potentiates the effect of INTROPIN. The starting dose in such patients should be reduced to at least one-tenth (1/10) of the usual dose.

Usage in Pregnancy—Animal studies have revealed no evidence of teratogenic effects from INTROPIN. The drug may be used in pregnant women when, in the judgment of the physician, the expected benefits outweigh the potential for risk to the fetus.

Usage in Children—The safety and efficacy of this drug in children has not been established. INTROPIN has been used in a limited number of pediatric patients, but such use has been inadequate to fully define proper dosage and limitations for use. Further studies are in progress.

PRECAUTIONS: Prior to treatment with INTROPIN, hypovolemia should be fully corrected, if possible, with either whole blood or plasma as indicated.

If a disproportionate rise in the diastolic pressure (i.e., a marked decrease in the pulse pressure) is observed in patients receiving INTROPIN, the infusion rate should be decreased and the patient observed carefully for further evidence of predominant vasoconstrictor activity, unless such an effect is desired.

Although in clinical trials inadvertent subcutaneous infiltration did not produce any evidence of necrosis, the usual precautions should be taken to avoid extravasation.

Close monitoring of the following indices—urine flow, cardiac output and blood pressure—during INTROPIN infusion is necessary as in the case of any adrenergic agent.

ADVERSE REACTIONS: The most frequent adverse reactions observed in clinical evaluation of INTROPIN included ectopic beats, nausea, vomiting, tachycardia, anginal pain, palpitation, dyspnea, headache, hypotension, and vasoconstriction. Other adverse reactions which have been reported infrequently were aberrant conduction, bradycardia, piloerection, widened QRS complex, azotemia, and elevated blood pressure.

DOSAGE AND ADMINISTRATION:

WARNING: THIS IS A POTENT DRUG. IT MUST BE DILUTED BEFORE ADMINISTRATION TO PATIENT.

Suggested Dilution—Transfer contents of one ampul (5 ml. containing 200 mg. INTROPIN) by aseptic technique to either a 250 ml. or 500 ml. bottle of one of the following sterile intravenous solutions:

1) Sodium Chloride Injection, USP
2) Dextrose 5% Injection, USP
3) Dextrose (5%) and Sodium Chloride (0.9%) Injection, USP
4) 5% Dextrose in 0.45% Sodium Chloride Solution
5) Dextrose (5%) in Lactated Ringer's Solution
6) Sodium Lactate (1/6 Molar) Injection, USP
7) Lactated Ringer's Injection, USP

These dilutions will yield a final concentration for administration as follows:

250 ml. dilution contains 800 mcg./ml. of INTROPIN

500 ml. dilution contains 400 mcg./ml. of INTROPIN

INTROPIN has been found to be stable for a minimum of 24 hours after dilution in the sterile intravenous solutions listed above. However, as with all intravenous admixtures, dilution should be made just prior to administration.

Do **NOT** add INTROPIN Injection to 5% Sodium Bicarbonate or other alkaline intravenous solutions, since the drug is inactivated in alkaline solution.

Rate of Administration—INTROPIN, after dilution, is administered intravenously through a suitable intravenous catheter or needle. An i.v. drip chamber or other suitable metering device is essential for controlling the rate of flow in drops/minute. Each patient must be individually titrated to the desired hemodynamic and/or renal response with INTROPIN. In titrating to the desired increase in systolic blood pressure, the optimum dosage rate for renal response may be exceeded, thus necessitating a reduction in rate after the hemodynamic condition is stabilized.

Administration at rates greater than 50 mcg/kg./min. have safely been used in advanced circulatory decompensation states. If unnecessary fluid expansion is of concern, adjustment of drug concentration may be preferred over increasing the flow rate of a less concentrated dilution.

Suggested Regimen:

1. When appropriate, increase blood volume with whole blood or plasma until central venous pressure is 10 to 15 cm H_2O or pulmonary wedge pressure is 14-18 mm Hg.

2. Begin administration of diluted solution at doses of 2-5 mcg./kg./minute INTROPIN in patients who are likely to respond to modest increments of heart force and renal perfusion.

In more seriously ill patients begin administration of diluted solution at doses of 5 mcg./kg./minute INTROPIN and increase gradually using 5 to 10 mcg./kg./minute increments up to 20 to 50 mcg./kg./minute as needed. If doses of INTROPIN in excess of 50 mcg./kg./minute are required, it is suggested that urine output be checked frequently. Should urine flow begin to decrease in the absence of hypotension, reduction of INTROPIN dosage should be considered. Multiclinic trials have shown that more than 50% of the patients were satisfactorily maintained on doses of INTROPIN less than 20 mcg./kg./minute. In patients who do not respond to these doses with adequate arterial pressures or urine flow, additional increments of INTROPIN may be employed in an effort to produce an appropriate arterial pressure and central perfusion.

3. Treatment of all patients requires constant evaluation of therapy in terms of the blood volume, augmentation of myocardial contractility, and distribution of peripheral perfusion. Dosage of INTROPIN should be adjusted according to the patient's response.

4. As with all potent intravenously administered drugs, care should be taken to control the rate of administration so as to avoid inadvertent administration of a bolus of drug.

OVERDOSAGE: In case of accidental overdosage, as evidenced by excessive blood pressure elevation, reduce rate of administration or temporarily discontinue INTROPIN until patient's condition stabilizes. Since INTROPIN's duration of action is quite short, no additional remedial measures are usually necessary. If these measures fail to stabilize the patient's condition, use of the short-acting alpha adrenergic blocking agent, phentolamine, should be considered.

HOW SUPPLIED: 5 ml. ampuls containing 40 mg. dopamine HCl per milliliter.

Five good reasons why Brush biomedical recording systems are your best buy.

1. Brush has a complete line of biomedical signal conditioners and recording systems.

We make a recorder/signal conditioner system to meet any biomedical recording need you may have.

For research monitoring OR, and Cath Lab you can choose from 1 to 8 channels on high performance direct writing recorders, XY recorders, 4 and 8 channel monitoring oscilloscopes, a light beam oscillograph with up to 16 channels.

Our engineered systems include all transducers, interconnecting cables, signal conditioning, recorders and direct display readouts.

2. The Brush pressurized inking system gives you the highest quality traces.

Brush traces are the standard of the industry. Our pressurized inking system eliminates smudges, smears, skips and puddles because the traces are actually forced into the paper. The record you get is crisp, clear and permanent.

3. Brush guarantees better than 99.5% linearity.

There are two reasons why we can guarantee such a high degree of accuracy. First, our Metrisite® non-contact servo-loop feedback device moves freely in an enclosed air gap. Second, our recorders have a rectilinear presentation rather than a curvilinear one. This eliminates geometric errors inherent with the conventional system.

4. Brush biomedical recording systems give you trouble free operation.

All of our instruments require minimal maintenance. For example, our disposable ink cartridge provides for a year's worth of recording. Our Metrisite tracing system eliminates slide wires and all the problems that go with them. And all of our electronics are solid state.

5. A Brush system is one of the easiest to operate.

All systems are self calibrating. Our controls are conveniently placed to give you maximum flexibility. Chart paper can be replaced in seconds. Switching signal conditioners is a snap. And Brush service technicians and engineers are readily available when and if you do need assistance.

Send for our free full color catalog. Write Gould Inc., Instrument Systems Division, 3631 Perkins Avenue, Cleveland, Ohio 44114. Or Kouterveldstraat Z/N, B 1920 Diegem, Belgium.

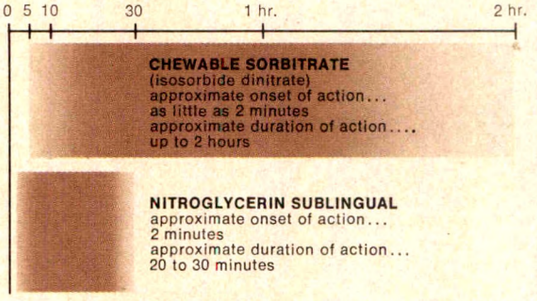
A walk without worr
Grandpa
has two hours
of angina protection.
CHEWABLE
SORBITRATE®
ISOSORBIDE DINITRATE 5MG.
goes beyond the
benefits of sublingual
nitroglycerin

For up to two hours of protection, your angina patient needs *more* than sublingual nitroglycerin. And Chewable Sorbitrate provides more.

☐ Acts almost as fast as nitroglycerin... lasts about 4 times as long.



☐ More stable in air than sublingual nitroglycerin: it can be stored or carried with no significant loss of potency.

☐ And when indicated: Sorbitrate® (isosorbide dinitrate) Sublingual 5 mg. and 2.5 mg.

SUMMARY OF PRESCRIBING INFORMATION

Mode of action: The mechanism of action of SORBITRATE (isosorbide dinitrate) is unknown, although the basic pharmacologic action is to relax smooth muscle. Isosorbide dinitrate reduces in number and severity the incidence of angina pectoris attacks, with concomitant reduction in nitroglycerin intake.

Indications: Sublingual and Chewable: For the prevention and treatment of angina pectoris.

Oral: For the relief of angina pectoris. It is not intended to abort the acute anginal episode. SORBITRATE WITH PHENOBARBITAL is indicated for patients in whom the angina pectoris is accompanied by anxiety or its related symptoms.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety. Phenobarbital may be habit forming.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: Route: Sublingual, oral and chewable tablets.

Individual Dose: To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg. Sublingually or orally, 5 to 10 mg. is the range commonly used although doses of up to 30 mg. have frequently been employed.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an anginal attack. Sublingual SORBITRATE may be taken p.r.n. or at 4 to 6 hour intervals; Oral SORBITRATE may be taken 3 to 4 times daily. CHEWABLE SORBITRATE may be taken for prompt relief of anginal pain 3 or 4 times daily. Although the onset and duration of effect of coronary nitrates may vary, following are the generally reported ranges of these values for SORBITRATE:

Onset of Effect: Sublingual and Chewable: 2 to 5 minutes. Oral: 15 to 30 minutes.

Duration of Effect: Sublingual and Chewable: 1 to 2 hours. Oral: Estimated to be 4 to 6 hours.

It is recommended that the oral dosage be taken on an empty stomach.

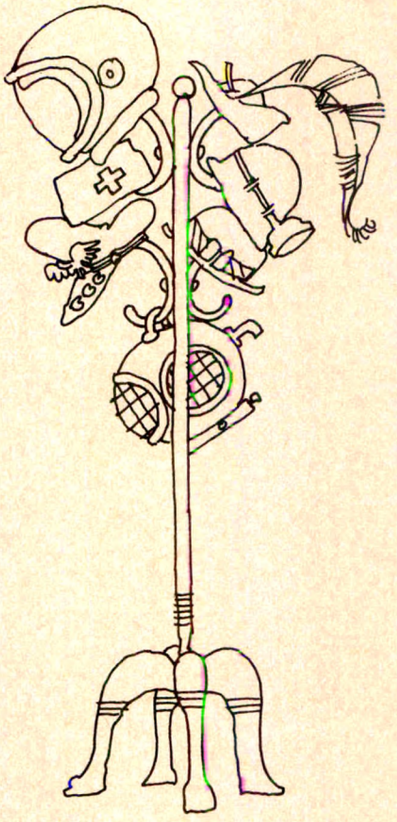
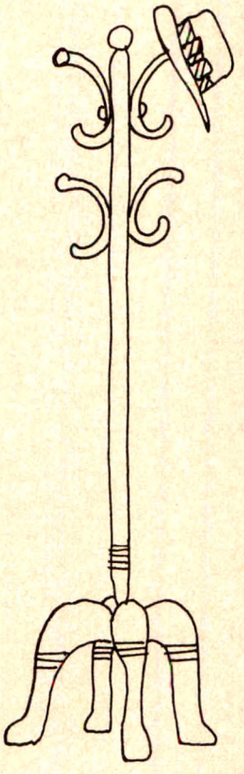
WILMINGTON, DEL. 19899

The hat rack syndrome:



The cure:



Some companies make medical instruments—and pocket calculators, light bulbs, computers, hair dryers, x-ray systems, washing machines, you name it.

B-D Electrodyne makes medical instruments. Period.

Does our specialization seem odd, in this Day of The Multi-Line Manufacturer? Maybe so. But it's also how we came to pioneer the patient monitoring system.

And it's quite basic, when you think about it.

All our R&D, *all* our production, *all* our testing, *all* our service facilities are single-mindedly devoted to medical instrumentation.

In addition, we're backed by a parent company—Becton, Dickinson—the #1 in hospital equipment for more than 75 years. So our patient monitoring systems, for example, are *bound* to be pretty darned good.

B-D Electrodyne. Sure, we wear only one hat. But it's the top hat. We'll be delighted to tell you all about it. B-D ELECTRODYNE, Division of Becton, Dickinson and Company, Sharon, Mass. 02067. Phone: (617) 828-9080.

At the first sign of trouble

Pronestyl® Tablets

(Procainamide Hydrochloride Tablets)

The prolonged administration of procainamide often leads to the development of a positive anti-nuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative anti-arrhythmic therapy.

Pronestyl Tablets (Procainamide Hydrochloride Tablets) are veneer-coated tablets providing 250 mg., 375 mg., and 500 mg. procainamide hydrochloride.

CONTRAINDICATIONS: In patients with myasthenia gravis and where a hypersensitivity to procainamide exists; bear in mind cross sensitivity to procaine and related drugs. Should not be given to patients with complete atrioventricular heart block. Contraindicated in cases of second degree and third degree A-V block unless an electrical pacemaker is operative.

ADMINISTRATION: Should procainamide therapy be continued for any appreciable period, electrocardiograms should be made occasionally to determine its further need.

PRECAUTIONS: Evidence of untoward myocardial response should be carefully watched for in all patients. In the presence of myocardial damage with atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed; adequate digitalization reduces but does not abolish this danger. Ventricular tachysystole is particularly hazardous if myocardial damage exists.

The dislodgement of mural thrombi producing an embolic episode may occur in correcting atrial fibrillation due to the forceful contractions of the atrium.

Extreme caution is required in attempting to adjust the heart rate when ventricular tachycardia has occurred during an occlusive coronary episode or where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation as in second degree and third degree A-V block, bundle branch block, or severe digitalis intoxication.

Bear in mind when treating ventricular arrhythmias in patients with severe organic heart disease and ventricular tachycardia that complete heart block, which may be difficult to diagnose, may be present. Since asystole may result if the ventricular rate is significantly slowed without attainment of regular atrioventricular conduction, procainamide should be stopped and the patient re-evaluated.

In the presence of both liver and kidney damage, normal dosage may produce symptoms of overdosage—principally ventricular tachycardia and severe hypotension.

A syndrome resembling lupus erythematosus has been reported with maintenance procainamide therapy. Common symptoms are polyarthralgia, arthritis and pleuritic pain. Fever, myalgia, skin lesions, pleural effusion and pericarditis may also occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia, possibly related to this syndrome, have been reported. Measure antinuclear antibody titers at regular intervals in patients on procainamide for extended periods of time or in whom symptoms suggestive of lupus-like reaction appear; in event of rising titer (anti-nuclear antibody) or clinical symptoms of LE, assess the benefit/risk ratio related to continued procainamide therapy (see boxed Warning). Steroid therapy may be effective if discontinuation of procainamide does not cause remission of symptoms. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not otherwise controllable, steroid-suppressive therapy may be used concomitantly with procainamide.

ADVERSE REACTIONS: Hypotension is rare with oral administration. Serious disturbances of cardiac rhythm such as ventricular asystole or fibrillation are more common with I.V. administration.

Large oral doses may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

A syndrome resembling lupus erythematosus has been reported (see Precautions). Reactions consisting of fever and chills have been reported, including a case with nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Agranulocytosis has been occasionally reported following repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy; and the patient should be instructed to report any soreness of the mouth, throat or gums, unexplained fever or any symptoms of upper respiratory tract infection. If any of these symptoms should occur and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately. Bitter taste, diarrhea, weakness, mental depression, giddiness, psychosis with hallucinations, and hypersensitivity reactions such as angioneurotic edema and maculopapular rash have been reported.

The package insert should be read carefully to become familiar with the recommended dosage for the indicated conditions and for full prescribing information.

HOW SUPPLIED: Pronestyl Tablets (Procainamide Hydrochloride Tablets) providing 250 mg., 375 mg., and 500 mg. are available in bottles of 100.

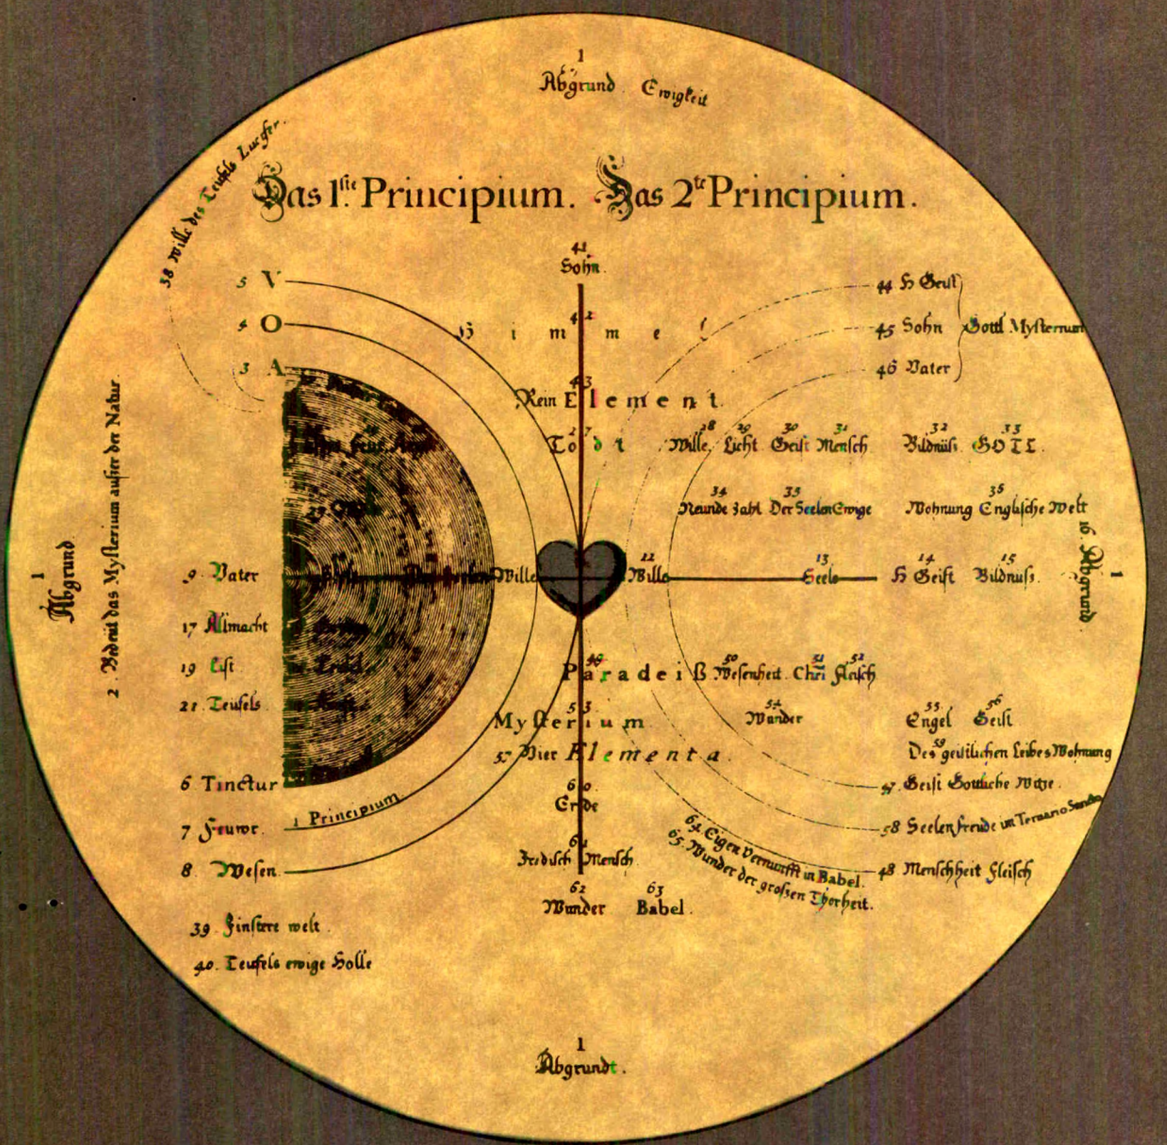
Die Philosophische Kugel oder das Wunder-Auge der Ewigkeit.



The art of antianginal therapy

For centuries, treating the heart's ills has been the subtlest of arts. Even today, evaluating a drug for chronic angina pectoris involves the art of medicine as well as its science.

Persantine — over a decade of use

During more than a decade of clinical experience, compounding both science and art, Persantine has often been found useful in the long-term management of chronic angina pectoris.* It may:

eliminate or reduce the frequency of anginal attacks

improve exercise tolerance

reduce nitroglycerin requirements

Persantine — give enough — long enough

The recommended dosage: 50 mg. t.i.d. at least one hour before meals. *Give enough, long enough* — several weeks or longer of continuous therapy may be needed to see response.

Persantine® Tablets of 25 mg.

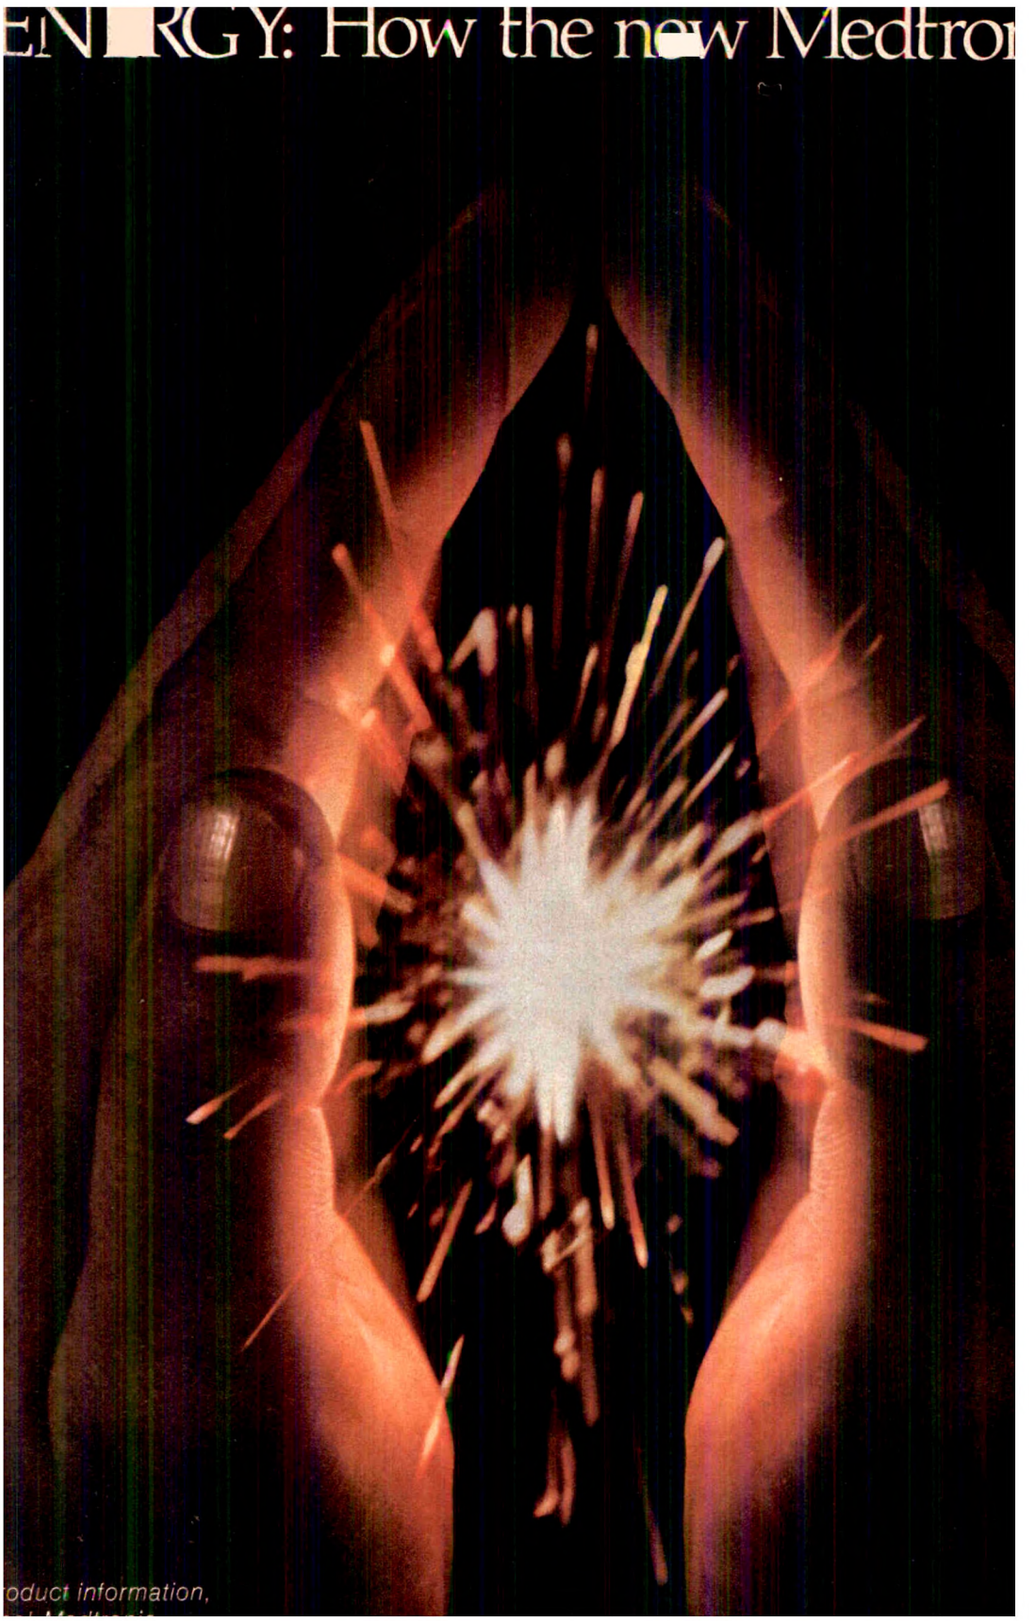
BOEHRINGER INGELHEIM

Boe
Ing

Boehringer I
Elmsford, Ne



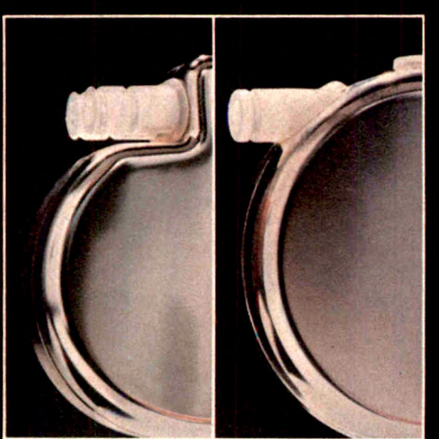
ENERGY: How the new Medtron
oduct information,

pacemakers conserve it.

The concept of Energy Conservation is based on one simple fact: lessen the drain on a power source and you extend its life.

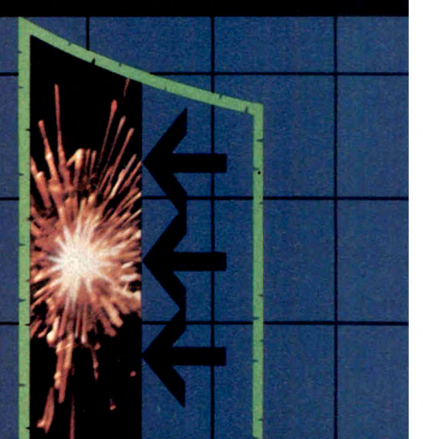
In the new Medtronic pacemakers, pulse width has been reduced to reduce the energy expenditure per pulse.

Less energy expended means longer projected life. It's that simple.



Model 5944— Bipolar Demand Pulse Generator

Model 5945— Unipolar Demand Pulse Generator

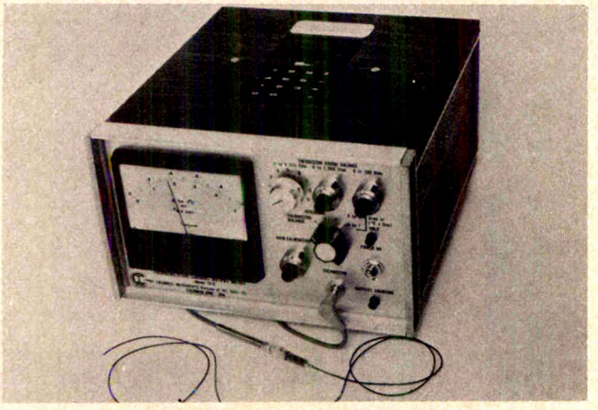


As pulse width narrows, projected life of the pulse generator is extended

Another significant improvemen combines the idea of energy compensation with a redundant cell depletion indicator. It works this way: when depletion of the first cell occurs the new Medtronic pulse generators show a decrease in rate similar to most other pulse generators. But, the also automatically increase pulse width when depletion occurs. This increase in pulse width compensate

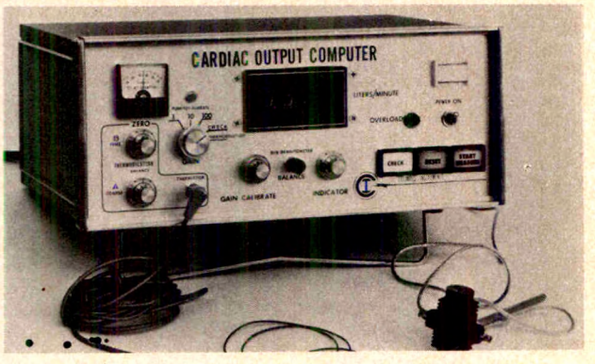
THERMODILUTION

Using room temperature indicator!



THERMODILUTION CARDIAC OUTPUT METER AND INTEGRATOR

- An intermediate instrument between the simple bridge and full scale computer.
- Battery operated—no shock hazards. Rechargeable.
- Will work with any thermistor catheter on the market; including Swan-Ganz balloon flow-directed catheter.
- Equipped with a recorder output.
- Provides information on the area under the dilution curve. (Extrapolates the dilution curve!)
- Price: $1,540.00



THERMO AND DYE DILUTION CARDIAC OUTPUT COMPUTER

- Equipped with Thermodilution and/or Dye Dilution Densitometer
- Easy calibration, automatic zeroing.
- Remote control by foot switch.
- Digital readout in L/min.
- Recorder outputs.

COLUMBUS INSTRUMENTS

Div. of International Instruments Co.

P. O. Box 5244 Columbus, Ohio 43212
Telephone: (614) 488-6176

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation or in women of childbearing age requires that its potential benefits be weighed against its possible hazards.

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

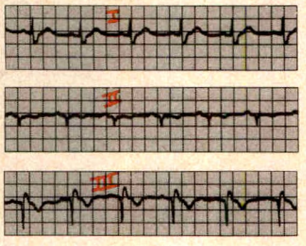
Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

ROCHE

Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, N.J. 07110

The Somatic Protest in the Postcoronary Patient...

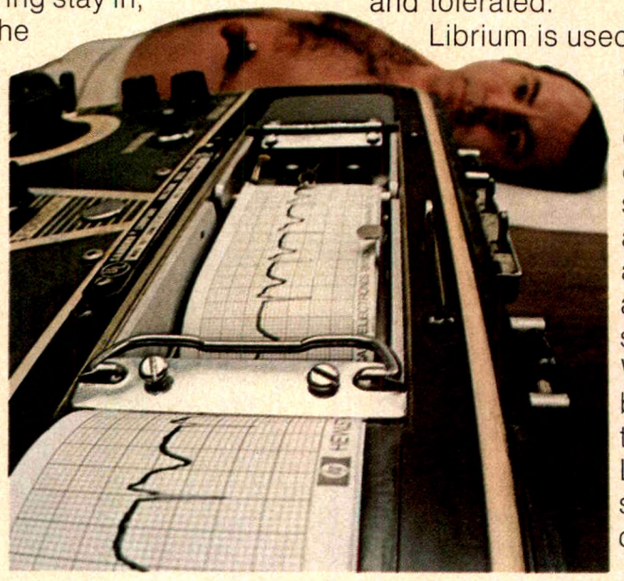
Physiologic reaction to excessive anxiety



Although he has valid reason for concern, the person convalescing from myocardial infarction may react to his illness with *disproportionate* anxiety, which can hinder smooth recovery and rehabilitation. Undue anxiety and emotional tension may, in some patients—because of marked increase in catecholamine excretion during stay in, and on day of transfer from, the CCU—cause increased heart rate, increased cardiac output and intensified oxygen consumption by heart muscle. In addition, excessive anxiety can (1) increase feelings of frustration at forced inactivity, (2) foster undue preoccupation with heart function, (3) diminish capacity to tolerate prospect of work stress and (4) retard rehabilitation. A calm outlook and reduction of excessive emotional stress are thus desirable.

Antianxiety action with wide margin of safety

Adjunctive antianxiety medication, when needed to complement counseling and reassurance, should be both effective and comparatively free from undesirable side effects. Extensive clinical experience has demonstrated that Librium (chlordiazepoxide HCl) fulfills these requirements with a high degree of consistency. In the elderly and debilitated, the initial dose is 5 mg *b.i.d.* or less to preclude ataxia or oversedation, increasing gradually as needed and tolerated.



Librium is used concomitantly with certain specific medications of other classes of drugs, *e.g.*, cardiac glycosides, diuretics and antihypertensive agents, whenever anxiety is a clinically significant factor. When anxiety has been reduced to tolerable levels, Librium therapy should be discontinued.

adjunctive

ROCHE

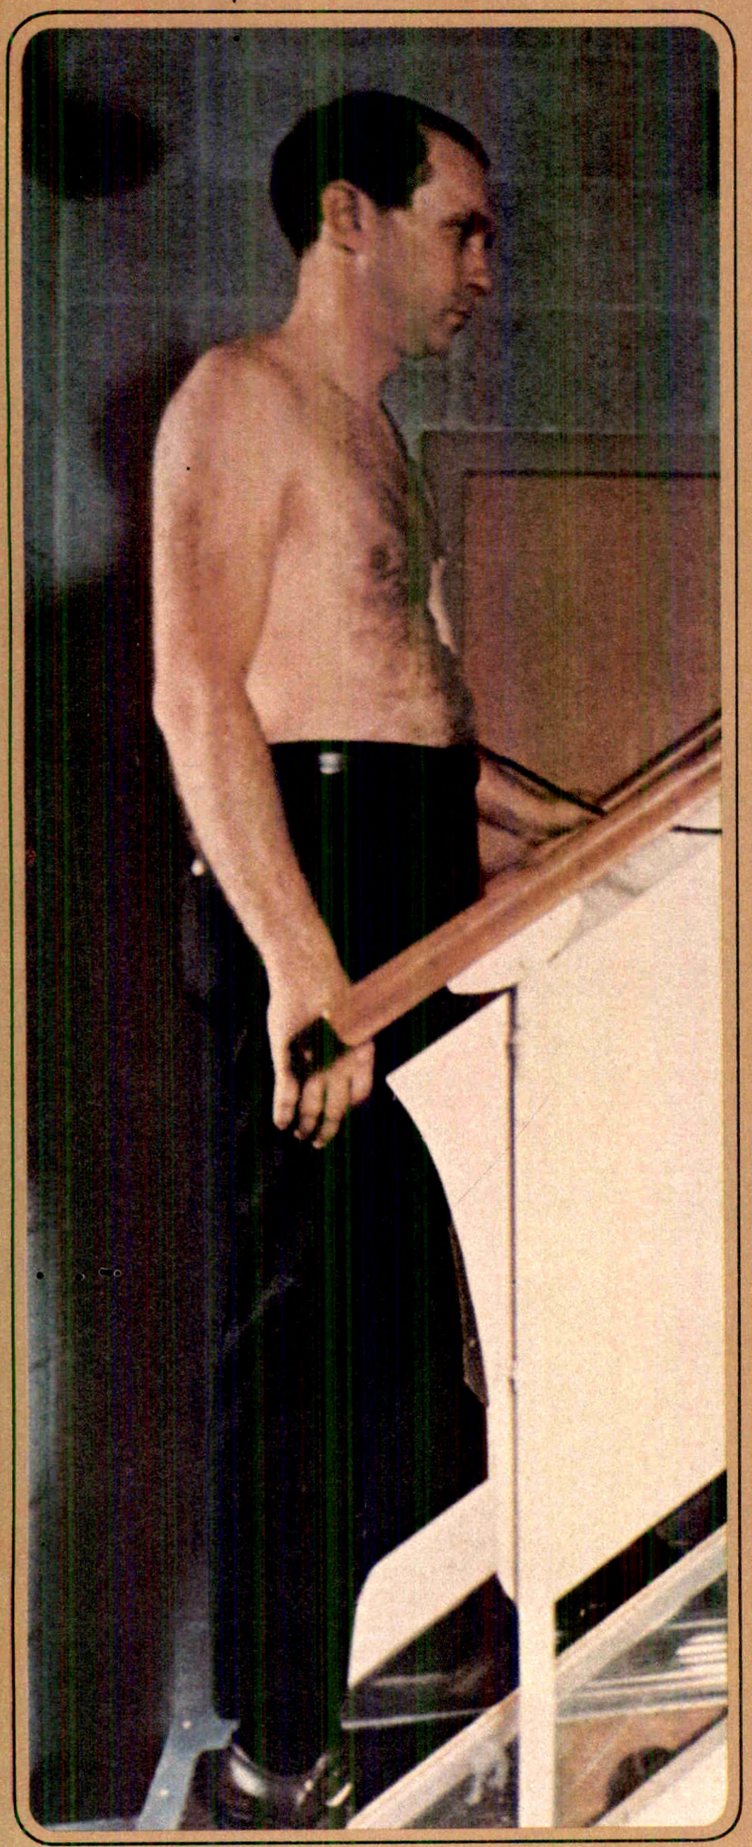
Librium® 10 mg

(chlordiazepoxide HCl)

1 or 2 capsules t.i.d./q.i.d.

Please see opposite page for summary of product information.

A47



tolerance to exercise improved for angina patients

INDICATIONS: For the prophylaxis and long-term management of patients with frequent or recurrent anginal pain and reduced exercise tolerance associated with angina pectoris, rather than for the treatment of the acute attack of angina pectoris, since its onset of action is somewhat slower than that of nitroglycerin.

PRECAUTIONS: As with other effective nitrites, some fall in blood pressure may occur with large doses. Caution should be observed in patients with a history of recent cerebral hemorrhage, because of the vasodilatation which occurs in the area. Although therapy permits more normal activity, the patient should not be allowed to misinterpret freedom from anginal attacks as a signal to drop all restrictions.

SIDE EFFECTS: No serious side effects have been reported. As with nitroglycerin or other effective nitrites, temporary vascular headache may occur during the first few days of therapy. This can be controlled by temporary dosage reduction in order to allow adjustment of the cerebral hemodynamics to the initial marked cerebral vasodilatation. These headaches usually disappear within one week of continuous therapy but may be minimized by the administration of analgesics such as Empirin® Compound.

Mild gastrointestinal disturbances occur occasionally with larger doses and may be controlled by reducing the dose temporarily.

SUPPLIED: 10 mg. chewable tablets. Bottles of 100. Also 5, 10 and 15 mg. scored tablets in bottles of 100. 10 mg. scored tablets also supplied in bottles of 1000.

Also available: Cardilate-P brand Erythrityl Tetranitrate with Phenobarbital (Warning: may be habit-forming).

Cardilate®
(erythrityl tetranitrate)

chewable tablets 10 mg.

CLINICAL STUDIES

Hemodynamic Effects of Noninvasive Systolic Unloading (Nitroprusside) and Diastolic Augmentation (External Counterpulsation) in Patients with Acute Myocardial Infarction

WILLIAM W. PARMLEY, MD, FACC*
KANU CHATTERJEE, MB, MRCP, FACC
YZHAR CHARUZI, MD
H. J. C. SWAN, MD, PhD, FACC

Los Angeles, California

The two major beneficial hemodynamic effects of invasive circulatory assistance (intraaortic balloon pumping) are (1) left ventricular systolic unloading, and (2) diastolic augmentation of aortic pressure. In this study, these effects were produced noninvasively in 17 patients (13 with acute myocardial infarction, 5 of whom had cardiogenic shock). Systolic unloading produced by the constant intravenous infusion of sodium nitroprusside (16 to 200 μg/min) caused a reduction in pulmonary capillary wedge pressure (27 to 19 mm Hg), a rise in cardiac index (1.71 to 2.25 liters/min per m^2), and a reduction in mean arterial pressure (81 to 73 mm Hg). Diastolic augmentation with external counterpulsation produced a 20 mm Hg increase in peak, and a 7 mm Hg increase in mean diastolic arterial pressure. Cardiac index rose 14 percent after external counterpulsation in the patients with acute myocardial infarction. The results of combined use of these two modes of therapy (nitroprusside plus external counterpulsation) were better than those of either alone, in that external counterpulsation reversed the decrease in diastolic arterial pressure produced by nitroprusside, and also increased cardiac index further in six of nine patients. Thus it is feasible to utilize the principles of invasive circulatory assistance in a noninvasive way to produce hemodynamic improvement in patients with acute myocardial infarction.

The two major beneficial hemodynamic effects of invasive circulatory assistance appear to be (1) left ventricular systolic unloading, and (2) diastolic augmentation of aortic pressure. Systolic unloading permits an increased stroke volume at the same end-diastolic fiber length and also reduces myocardial oxygen demand by reducing the tension-time index. Subsequent reduction in heart size due to more complete systolic emptying will further reduce myocardial oxygen demand. By contrast, diastolic augmentation increases coronary perfusion pressure and thus helps to maintain coronary flow, particularly in the presence of partial obstruction of the coronary arteries.

Devices such as the intraaortic balloon which produce these two effects have been shown to have beneficial effects in some patients with

acute myocardial infarction and pump failure.[1] However, the use of these invasive devices for circulatory assistance requires a specially trained surgical-medical team and has generally been restricted to selected research centers. If similar hemodynamic effects could be obtained in a noninvasive manner, such benefit would be more widely applicable to patients with pump failure after acute myocardial infarction.

Several recent studies have shown that systolic unloading with vasodilator drugs such as nitroprusside or phentolamine can improve hemodynamic performance in pump failure complicating acute myocardial infarction.[2–5] However, such agents also reduce arterial diastolic pressure because of their nonselective action relative to the cardiac cycle. This reduction in the coronary arterial perfusing pressure might further compromise coronary blood flow and produce hemodynamic deterioration. On the other hand, noninvasive external counterpulsation has been found to be effective in increasing diastolic perfusing pressure.[6] A combination of these two therapeutic maneuvers might complement each other and thus provide a simple, noninvasive application of the principles of invasive circulatory assistance. Accordingly, this study was designed to determine the separate and combined effects of these two therapeutic modalities on hemodynamics and cardiac metabolism in patients with acute myocardial infarction.

Methods

Patient population and measurements: Seventeen patients underwent external counterpulsation (Cardiassist®, Medical Innovations, Inc., Waltham, Mass.) for at least 1 hour. Thirteen of these patients had acute myocardial infarction, and 5 of the 13 had clinical cardiogenic shock. The four patients without infarction included two with coronary artery disease and two with cardiomyopathy (Table I). Control hemodynamic measurements were obtained after admission of the patients to the Myocardial Infarction Research Unit. Arterial pressure (AP) was monitored through a 20 gauge cannula inserted into the radial artery. Right atrial (RA), pulmonary arterial (PA) and pulmonary capillary wedge (PCW) pressures were recorded through a balloon-tipped catheter.[7] At least five pressure cycles were measured and averaged for each single reading. Cardiac output (CO) was measured by the thermodilution technique in triplicate with the same catheter. Individual variation in triplicate measurements is generally 5 to 10 percent. In seven patients, coronary sinus flow was measured by a constant infusion thermodilution technique.[8] Minute to minute variation in this measurement is 5 to 10 percent if hemodynamic status remains stable. For this determination a special preshaped catheter was inserted into the coronary sinus. Blood samples from the coronary sinus and radial artery were analyzed for pH, PCO_2, and PO_2 by a pH gas analyzer (model 113, Instrumentation Laboratories). Hemoglobin saturation was determined with a co-oximeter (model 182, Instrumentation Laboratories, Lexington, Mass). The mean difference between paired samples was less than 1 percent. Samples of arterial and coronary sinus blood were also obtained for determination of lactate concentration by an automated modification of the enzymatic method of Hohorst.[9]

Derived hemodynamic and metabolic measurements were calculated as follows: Stroke work index (SWI) = stroke volume index (SVI) × ($\overline{AP}$ − $\overline{PCW}$) × 0.144 (g-m/m^2); systemic vascular resistance (SVR) = 80 ($\overline{AP}$ − $\overline{RA}$)/CO (dynes sec cm^{-5}); oxygen content (ml/100 ml) = hemoglobin saturation × hemoglobin content (g/100 ml) × 1.34;

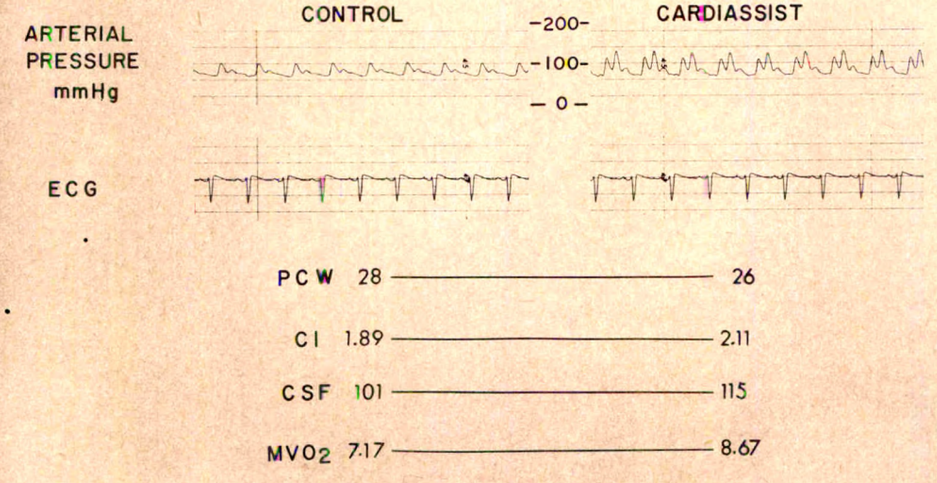

FIGURE 1. Tracings before and during external counterpulsation in a representative patient with acute myocardial infarction and moderate pump failure. Diastolic augmentation of pressure is seen in the arterial pressure tracing at right. CI = cardiac index (liters/min per m^2); CSF = coronary sinus flow (ml/min); ECG = electrocardiogram; MVO_2 = myocardial oxygen consumption (ml/min); PCW = pulmonary capillary wedge pressure (mm Hg).

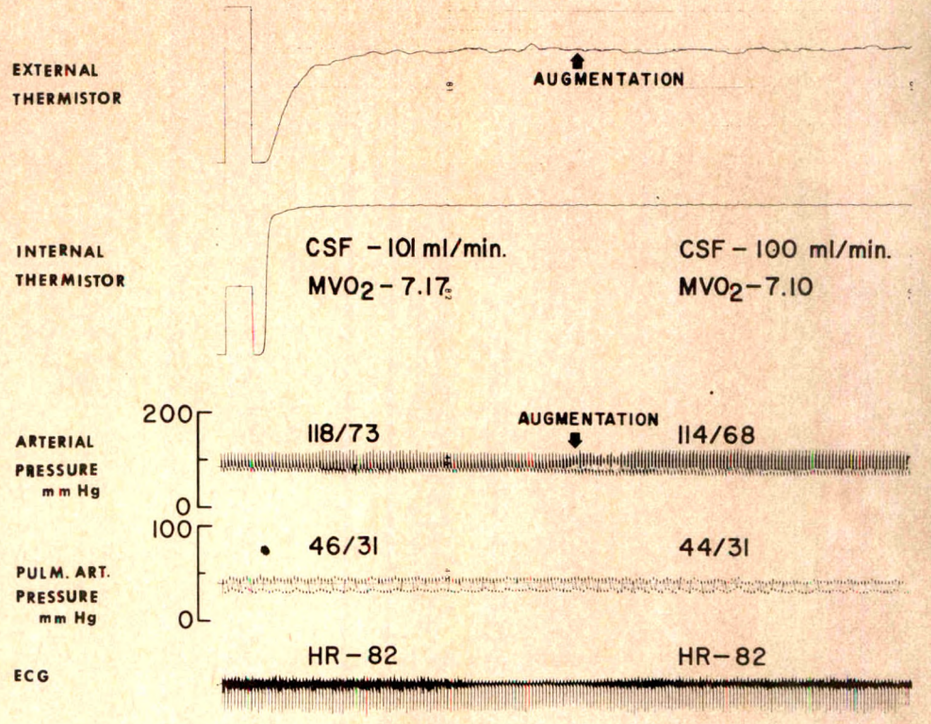

FIGURE 2. Tracings obtained during the measurement of coronary sinus flow in a representative patient with acute myocardial infarction. The upper two tracings represent temperature recordings from the external and internal thermistors of the coronary sinus catheter. After initial calibration there was a continuous infusion of cold 5 percent dextrose in water until a constant temperature and flow rate (101 ml/min) were achieved. Diastolic augmentation was initiated at the **arrow.** HR = heart rate (beats/min); PULM. ART. = pulmonary arterial; other abbreviations as in Figure 1.

myocardial oxygen consumption (ml/min) = [arterial-coronary sinus oxygen content (ml/100 ml)] × [coronary sinus blood flow (ml/min) × 10^{-2}]; myocardial lactate extraction (percent) = (arterial-coronary sinus lactate)/arterial lactate.

Systolic unloading with nitroprusside: Nitroprusside was administered intravenously at a rate of 16 to 200 μg/min with the use of an infusion flow controller (Ivac 200, Ivac Corporation, San Diego, Calif.). The infusion rate of nitroprusside was gradually increased until the mean arterial pressure decreased by not more than 20 mm Hg or until there was a significant decrease (more than 5 mm Hg) in the pulmonary capillary wedge pressure. The infusion rate of nitroprusside was then kept constant, and hemodynamic and metabolic measurements were repeated. Patients were given maintenance doses of nitroprusside for a minimum of several hours, and in many instances for periods ranging up to several days.

Diastolic augmentation with external counterpulsation: The Cardiassist device was placed over the lower legs of the patient and adjusted comfortably. External counterpulsation synchronized with the electrocardiogram was applied in diastole to produce satisfactory visual augmentation of the arterial diastolic pressure on the oscilloscope. External counterpulsation pressures ranged from 150 to 250 mm Hg depending on patient comfort and the hemodynamic results.

After initial hemodynamic measurements, external counterpulsation was applied for at least 1 hour. Hemodynamic measurements were then repeated while the assist device was in use. In the nine patients who subsequently received nitroprusside, the external counterpulsation was discontinued and the hemodynamic measurements were repeated. During nitroprusside administration hemodynamic measurements were obtained and then external counterpulsation was added for periods of 1 hour to evaluate the additive effects of the two modalities on hemodynamics. In general, nitroprusside therapy was used as the primary therapeutic intervention, whereas external counterpulsation was added periodically.

Results

Results of External Counterpulsation

Figure 1 illustrates the representative hemodynamic effects of external counterpulsation in a patient with myocardial infarction and moderate pump failure. The augmentation of diastolic pressure is illustrated in the right panel of the arterial pressure tracing. During external counterpulsation, this patient had a slight increase in systolic pressure, with no change in heart rate or pulmonary capillary wedge pressure. There was a 10 percent increase in cardiac index. The slight increase in coronary sinus flow and myocardial oxygen consumption ($M\dot{V}O_2$) was probably secondary to the increase in systolic pressure and time-tension index.

When there was little change in the systolic pressure, external counterpulsation and diastolic augmentation did not, in general, appear to affect the level of coronary sinus flow, as shown by tracings from a representative patient in Figure 2. External counterpulsation with diastolic augmentation, was begun at the arrow. The temperature record of the external thermistor **(top panel)** was not altered by diastolic augmentation although mean diastolic pressure was increased by 7 mm Hg. Thus, coronary sinus flow and $M\dot{V}O_2$ were unchanged.

Figure 3 shows the effects of external counterpulsation on peak and mean diastolic pressures in all patients studied. There was a statistically significant

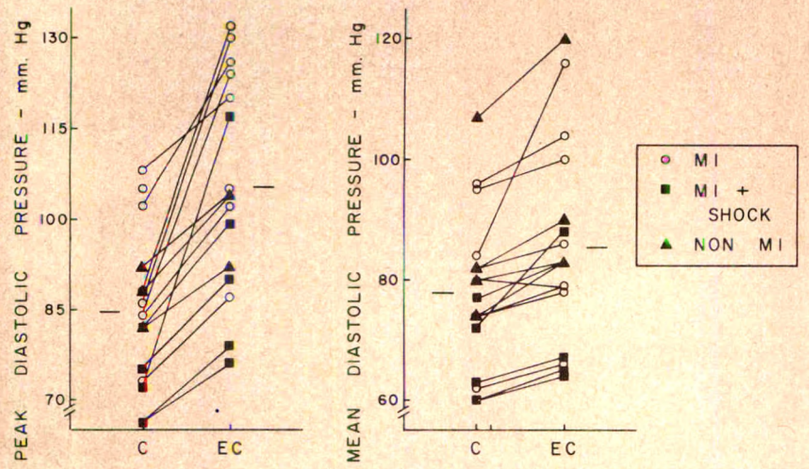

FIGURE 3. Effects of external counterpulsation (EC) on arterial diastolic pressure in three subgroups of patients. Individual patients before (C) and during external counterpulsation are indicated by the appropriate symbols connected by a line. The lines to the side of the data indicate the means for the entire group. MI = myocardial infarction.

increase in peak (average 20 mm Hg) and in mean (7 mm Hg) diastolic pressure. The combined hemodynamic effects of external counterpulsation in all patients are summarized in Table II. In both groups of patients with myocardial infarction, there was also a statistically significant increase in cardiac index (average 14 percent) and in stroke work index (average 25 percent). There were no significant changes in heart rate or right and left ventricular filling pressures. Similarly, there were no significant changes in coronary sinus flow, $M\dot{V}O_2$ or lactate extraction (Table III).

Effects of Nitroprusside and External Counterpulsation

Figure 4 illustrates the representative effects of nitroprusside alone and combined therapy with nitroprusside and external counterpulsation in a patient with acute myocardial infarction. With nitroprusside alone, there was a slight reduction in arterial pressure from 110/75 to 104/65 mm Hg. The pulmonary capillary wedge pressure decreased from 28 to 18 mm Hg, and cardiac index rose from 1.76 to 2.39 liters/min per m^2. The addition of external counterpulsation during nitroprusside administration (right panel) resulted in restoration of mean diastolic pressure to control levels, a further small increase in cardiac index, and no further change in heart rate or left ventricular filling pressure.

The effects of these two interventions on arterial pressure in all patients are illustrated in Figure 5. Nitroprusside alone produced a reduction in both mean and diastolic arterial pressures. The addition of external counterpulsation did not further alter mean arterial pressure, but greatly augmented peak diastolic pressure and returned mean diastolic pressure to control values (Table IV).

Figure 6 illustrates other hemodynamic effects of these two interventions. Nitroprusside alone produced a significant reduction in pulmonary capillary wedge pressure and an increase in cardiac index. The addition of external counterpulsation to treatment with nitroprusside did not significantly alter any of these variables (Table IV) although in six of nine patients it consistently produced a further slight augmentation of cardiac index. This is illustrated in Figure 7, which shows serial hemodynamic data in one patient during a 3 day period. External counterpulsation was the initial therapy for 1 hour. Following this, nitroprusside was the predominant therapy for several days. At different time intervals, external counter-

pulsation was subsequently added to nitroprusside as indicated by the brackets labeled EC. External counterpulsation by itself, and when added to nitroprusside therapy, always produced a slight further increase in cardiac index. The reduction in pulmonary capillary wedge pressure and rise in cardiac index produced by administration of nitroprusside were abruptly reversed when the drug was discontinued and promptly returned when it was reinstituted (on 7-14 for example). There was a gradual rise in cardiac index over the first 3 days, which is characteristic of patients with severe pump failure who subsequently survive after nitroprusside therapy.[5]

Clinical course: There were no perceptible changes in the clinical condition of the patients with external counterpulsation alone, but administration of nitroprusside usually resulted in clinical improvement. This was manifested as a decrease in dyspnea as the pulmonary capillary wedge pressure was reduced and a slight warming of the limbs as cardiac output increased. These clinical signs were quickly reversed when the nitroprusside therapy was discontinued, which prompted a continuous (1 to 5 days) infusion of nitroprusside in some patients, particularly to control dyspnea.

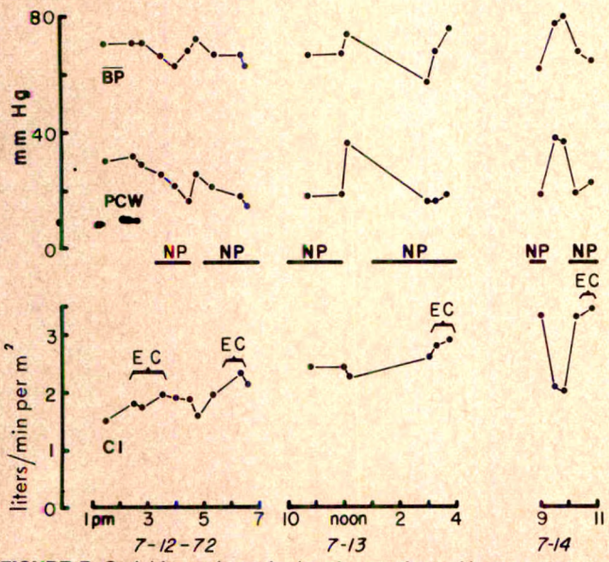

FIGURE 7. Serial hemodynamic data in a patient with severe pump failure after acute myocardial infarction. Mean arterial pressure ($\overline{BP}$), pulmonary capillary wedge pressure (PCW) and cardiac index (CI) are plotted as a function of time with representative samplings of 3 successive days included in the graph. The **solid line** (NP) indicates each period of nitroprusside infusion. The brackets labeled EC indicate each 1 hour period of external counterpulsation.

Although the number of patients in our study is too small to make conclusions about the effect of combined therapy on mortality (Table I), recent studies[5] with the use of nitroprusside alone have suggested a reduction in the mortality rate of cardiogenic shock from 85 to 40 percent.[5]

Discussion

Clinical use of invasive circulatory assist devices (intraaortic balloon) has produced beneficial hemodynamic effects in some patients, although the final result is often dependent on the initial degree of myocardial damage.[1] Because the insertion and operation of these devices require a specially trained team their application has been restricted to major research centers. Therefore, rapidly applicable *noninvasive* application of these same principles of circulatory assistance (systolic unloading and diastolic augmentation) is an attractive goal for physicians who do not have ready access to such centers.

Previous studies with drugs that decrease peripheral vascular resistance, such as phentolamine or nitroprusside, have suggested that beneficial hemodynamic effects can be obtained by systolic unloading in this manner.[2–5] Our findings also confirm that nitroprusside can produce a decrease in left ventricular filling pressure together with an increase in cardiac output and a reduction in myocardial oxygen demands.[5] The potential drawback to this therapy appears to be the reduction in diastolic perfusing pressure, which might compromise coronary blood flow, particularly if the level of arterial pressure is initially low. Accordingly, the simultaneous application of external counterpulsation to maintain diastolic perfusing pressure is an attractive concept. The critical level of coronary perfusing pressure has not been determined in man, and indeed is probably critically dependent on the degree of obstruction of the coronary circulation in each individual. Nevertheless, in most patients with pump failure, it is likely that aug-

mentation of diastolic pressure may protect against any potentially deleterious effects of nitroprusside infusion.

In this study, the hemodynamic effects of external counterpulsation consisted of a 7 mm Hg increase in mean diastolic pressure and a 14 percent rise in cardiac index. When external counterpulsation was added to nitroprusside therapy, diastolic pressure was returned to control levels, and in six of nine patients there was a further small rise in cardiac index. Thus, the combination of these two therapies appeared to be better than either one alone, although the predominant beneficial hemodynamic effects were produced by nitroprusside. Nitroprusside is valuable in patients with filling pressures greater than 15 mm Hg.[5] In patients with smaller initial filling pressures, nitroprusside caused tachycardia, accompanied by no change or a decrease in cardiac output.[5]

Clinical applications: In patients who arrive at the hospital with reduced arterial pressure, the immediate application of external counterpulsation may be a beneficial first step in increasing or at least maintaining vital coronary perfusion of ischemic myocardium. Once diastolic pressure has been augmented, it may then be possible to add nitroprusside therapy to reduce filling pressure, raise cardiac index and reduce myocardial oxygen consumption.

This combination therapy will also be beneficial for patients who have associated mitral regurgitation due to papillary muscle dysfunction. Nitroprusside[10] and intraaortic balloon counterpulsation[11] have each been effective in patients with mitral regurgitation, presumably because of their ability to produce systolic unloading. Diastolic augmentation may also help, however, if arterial pressure is reduced.

Drawbacks of external counterpulsation: Potential limitations of external counterpulsation include the discomfort that patients experience at high levels of pumping pressures for long periods of time (more than 2 to 3 hours). In most patients this discomfort necessitates application of the device in a periodic manner or at reduced pumping pressures that may diminish the degree of diastolic augmentation. External counterpulsation appears to be totally ineffective in patients with severe peripheral vascular disease. Local abrasions on the legs occurred in a few patients, but could be prevented by judicious placement of cotton padding. The use of external counterpulsation is also limited when there are tachyarrhythmias (rates higher than 150/min) or other serious rhythm disturbances that make it difficult for the timing and mechanical elements to follow the electrocardiographic signal. In general, however, the Cardiassist is easy to apply, reliable and immediately available for patients when they arrive at the hospital.

In summary, it appears possible to apply the principles of invasive circulatory assistance in a relatively noninvasive manner to patients with severe pump failure. The speed and ease of application may provide certain advantages in early reversal of the vicious cycle of increasing hypotension and poor coronary perfusion associated with cardiogenic shock. Although the major hemodynamic advantages appear to be related to systolic unloading with nitroprusside, the potential importance of maintaining arterial diastolic pressure is obvious and warrants continued investigation. The application of external compression to the lower limbs is patently a less effective means of altering aortic root dynamics than use of a displacement device positioned more proximally in the central arterial tree.[1] Nevertheless, the addition of external counterpulsation appears to produce sustaining levels of diastolic arterial support in seriously ill patients.

The predictive value of selected hemodynamic, metabolic, respiratory and renal variables was assessed in 29 patients with acute myocardial infarction complicated by shock. Arterial blood lactate was the most reliable variable individually and in combination with other variables. Individual measurements of blood flow were more reliable than measurements of blood pressure.

Prognostic indexes were derived using discriminant function analysis. Indexes based on current values of the variables were more useful than those utilizing repetitive values. Nonlinear combinations of arterial pressure and flow measurements did not provide a significant improvement over standard linear combinations. The use of the prognostic indexes provides an objective basis for assessing the severity of the patient's illness and his response to treatment.

In previous studies of prognostic indicators in patients with acute myocardial infarction and shock, the value of hemodynamic variables as predictors of survival was examined.[1] On the basis of data from 20 patients, stroke index emerged as the best single predictor. When two variables were combined in a linear manner, it was possible to increase the reliability of predicting survival. The best combination of two hemodynamic variables was stroke index and diastolic pressure. Inclusion of additional variables did not significantly improve reliability. In a later study[2] on patients with drug overdose, metabolic and respiratory variables were evaluated in addition to the hemodynamic variables. In this group of patients, systolic pressure was the best single predictor of survival, and systolic pressure and arterial pH was the best combination of two variables. Other variables, particularly arterial blood lactate levels, could be combined with systolic pressure to give comparable reliability.

These indexes were derived from single sets of concurrent measurements. However, it seemed reasonable to assume that the previous course of the patient might influence the prognosis. Accordingly, sequential sets of measurements were used to derive an accumulative prognostic index.[2] In patients with drug overdose, this index provided a more meaningful assessment of patient status and prognosis than that provided by concurrent measurements alone.

In this study of 29 patients with myocardial infarction and shock, metabolic, respiratory and renal variables were examined in addition to hemodynamic variables to determine their predictive value. Prognostic indexes based on groups of variables were derived. The efficacy of accumulative prognostic indexes also was evaluated.

Methods

Clinical Material

Twenty-nine patients with an acute myocardial infarction subsequently complicated by unequivocal clinical manifestations of shock were studied. In-

cluded were 22 men and 7 women ranging in age from 47 to 84 (median 64, mean 63.4) years. Seven of the patients recovered from the initial episode. On the patients' admission to the critical care ward, systolic pressure determined by the auscultatory technique was less than 80 mm Hg, the sensorium clouded, the skin clammy and urinary output less than 20 ml/hour. The clinical features are summarized in Tables I and II and the hemodynamic, respiratory and metabolic measurements in Table III. The electrocardiogram showed Q waves and S–T and T wave changes characteristic of acute transmural myocardial infarction in all but one patient. Serum glutamic oxaloacetic transaminase and lactic dehydrogenase were significantly increased in every patient. The heart was examined at autopsy in 13 patients, including the patient who had equivocal electrocardiographic changes. Acute transmural myocardial infarction with extensive muscle necrosis was confirmed in each case.

Patients were observed in the critical care ward for an average of 28 hours. The initial set of measurements was taken after discontinuation of treatment with vasoactive drugs. Subsequent measurements were obtained while patients were treated with standard therapeutic agents, including vasoactive drugs, cardiac glycosides and oxygen, at the discretion of the attending physician. The final set of observations consisted of the last measurements obtained before transfer of the patient to another ward, or before death exclusive of the agonal period.

some patients, individual variables were not measured because of technical considerations. For each patient, the first measurement of each variable was called the "initial" value and the last measurement before death or discharge, the "final" value. Values for arterial systolic and diastolic pressure, mean arterial pressure, mean central venous pressure, heart rate, peripheral vascular resistance, cardiac index, cardiac work, mean circulation time, appearance time, central blood volume and stroke index were obtained by previously described techniques.[3–5] Hourly urinary output was measured with the use of an automated urinometer attached to an indwelling urethral catheter. Rectal temperature was measured by means of thermistor probes.[6] Plasma volume was determined with ^{131}iodine- or ^{125}iodine-tagged iodinated serum albumin (RISA) and red cell mass with ^{51}chromium-tagged red blood cells.[7] Both of these values were standardized by weight to obtain plasma volume index and red cell index. Laboratory procedures used for measurement of hematocrit, hemoglobin, arterial pH, partial pressures of carbon dioxide, oxygen saturation and lactate have been described previously.[8,9]

Results

The outome with respect to specific clinical features is summarized in Table II. There was no statistically significant difference in survival rate for any of the clinical factors listed in Table II ($P > 0.10$). However, there were no survivors among patients with previous hypertension or congestive heart failure.

The statistical techniques used in our study assume that the values of the measured (continuous) variables follow normal distributions. To test the validity of this assumption, the empirical distribution of each variable was tested for normality by means of the chi-square goodness-of-fit test. All but six variables, cardiac index, appearance time, mean circulation time, plasma volume index, red cell index and arterial blood lactate, showed approximate normal distributions. Taking the logarithm of these variables produced approximate normal distributions.

Analysis of Single Variables

The *t* test was used to compare the mean values of the initial and final measurements in patients who survived the infarction with initial and final measurements in patients who died (Table III). Among the initial variables, arterial blood lactate, mean arte-

rial pressure, intraarterial diastolic pressure, arterial hematocrit and partial pressure of carbon dioxide showed a significant mean difference ($P < 0.05$). The final values of arterial hematocrit and partial pressure of carbon dioxide were not significant, although nine additional variables showed significant mean differences.

This analysis only demonstrates whether there were significant mean differences between patients who survived and patients who died. However, our interest lies mainly in determining the ability of each variable to predict whether the patient will survive his critical illness. To this end, a reference value was determined for each variable so that a patient would be classified as a survivor if his measured value exceeded the reference value. For certain variables, arterial blood lactate and appearance and mean circulation times, for example, a measured value of less than the reference value was indicative of survival. The procedure used to calculate the reference values is as follows[10]:

$$\text{Reference value} = (\text{mean value for survivors} + \text{mean value for nonsurvivors}) / 2$$

The measure of discriminating ability of a given variable is the Mahalanobis distance, which is defined as:

$$D^2 = (\text{mean value for survivors} - \text{mean value for nonsurvivors})^2 / \text{pooled variance}$$

where the pooled variance is calculated as the weighted average of the variances for survivors and patients who died. The Mahalanobis D^2 is a measure of the "distance" between the populations of survivors and nonsurvivors. The larger the value of D^2, the easier it is to correctly predict the patient's outcome. The percent probability of correct prediction, referred to as the reliability, is estimated as 100 times the area under the standard normal curve to the left of D/2.

Initial and final reference values and reliabilities were computed for each variable (Table IV). The sign preceding a reference value indicates the region in which survival is predicted. Thus, for example, a patient is predicted to survive if his initial systolic pressure is greater than 89 mm Hg; otherwise, he is predicted to die. Using this procedure of classification based on intraarterial systolic pressure alone, one would expect a correct prediction in 60 percent of cases. Among the initial values, arterial blood lactate was the most reliable single predictor (77 percent), followed by arterial hematocrit, partial pressure of carbon dioxide, mean arterial pressure and intraarterial diastolic pressure. The reliability of individual final values was generally greater than the corresponding reliability of initial values. Again, final values for arterial blood lactate were the most reliable (85 percent), followed by those for stroke work, urinary output, cardiac work and stroke index.

Analysis of Sets of Variables

The univariate analysis provides a measure of the prognostic ability of each variable separately. The statistical technique of discriminant function analysis[10] offers a method for combining values of several variables to predict

survival in an optimal way. Briefly, if one denotes the variables by $X_1, \ldots, X_k$, one forms the following linear discriminant function

$$Z = a_1X_1 + a_2X_2 + \ldots + a_kX_k$$

and can classify the patient as a survivor if Z is greater than the reference value. This discriminant function Z is derived by the addition of weighted values of the available variables. The weights $a_1, \ldots, a_k$ are chosen so that the probability of correct prediction is maximized. The reference value for Z is calculated as the average of the mean Z values for survivors and nonsurvivors. The Mahalanobis distance and reliability values are also readily estimated.[10] In this study, a stepwise discriminant analysis program[11] was used. The program first selected the single variable with the greatest reliability. The variable giving the greatest reliability when combined with the first variable was then selected, and so forth, until inclusion of additional variables did not significantly improve prediction.

Initial and final values were analyzed separately. The analysis was performed twice: once for the total group of 29 patients, in which case arterial blood lactate was not included as one of the variables, and again for a group of 24 patients whose arterial blood lactate values were available and were used in the analysis. Measurements of rectal temperature, urinary output, plasma volume index, red cell index, arterial hemoglobin, arterial hematocrit, arterial oxygen saturation and partial pressure of oxygen were not included in this phase of the analysis since only a few pa-

tients had measurements of all these variables. Because cardiac work and stroke work are derived nonlinear variables, they were also considered separately.

Initial values: Exclusive of arterial blood lactate, partial pressure of carbon dioxide in arterial blood had the greatest reliability of a single variable when initial values were used. When other single variables were combined with partial pressure of carbon dioxide, arterial pH contributed most to predicting survival. This improvement in reliability was statistically significant ($F = 4.9$, degrees of freedom 1, 26; $P < 0.05$). Of all the remaining variables, intraarterial diastolic pressure contributed most to this combination; however, this contribution was not statistically significant ($P > 0.10$). When arterial blood lactate was included, this variable was the most reliable. The variable that best contributed to arterial blood lactate was partial pressure of carbon dioxide. The improvement was of borderline statistical significance ($F = 3.9$, degrees of freedom 1, 21; $P < 0.06$). Other combinations of two variables that gave comparable reliability are shown in Table V.

Final values: Exclusive of arterial blood lactate, stroke index was the most reliable single variable when final values were used (Table IV). When other single variables were added, intraarterial diastolic pressure contributed most significantly ($F = 9.1$, degrees of freedom 1, 26; $P < 0.01$). Inclusion of additional variables did not significantly improve the reliability of prediction. When arterial blood lactate was included it was the best single predictor. Partial pressure of carbon dioxide was the only other variable that contributed to the reliability of arterial blood lactate. As with the initial values, this contribution was of borderline significance ($F = 3.7$, degrees of freedom 1, 21; $P < 0.07$). Other combinations of two variables that gave comparable reliability are shown in Table V.

Probability of Survival

To predict whether a patient will survive an acute episode, the discriminant function based on the final rather than the initial value is used, since the final values of survivors are more clearly separated from

those of patients who died. Instead of the discriminant function value, a clinically more meaningful assessment of the patient's status may be expressed in terms of the probability of survival, based on the value of a given variable or discriminant function. The probability of survival as a function of the value of arterial blood lactate is plotted in Figure 1. Thus, for a patient with an arterial blood lactate value of 2 millimoles, the likelihood of survival would be 73 percent. The formulas of the discriminant functions and the reference values, based on the best combinations of two variables, are shown in Table VI. For any discriminant function, the probability of survival may be read directly from the ordinate in Figure 2 by entering the difference between the reference and the discriminant function values on the abscissa. The probability of survival at any given time is referred to as the momentary prognostic index.

Accumulative Prognostic Indexes

The value of the discriminant function computed from current measurements does not necessarily reflect the previous course of the patient's illness. A more comprehensive assessment of the patient's status might take into account previous values of the discriminant function. For each of the 29 patients, intraarterial diastolic pressure and stroke index were used to compute the final discriminant function every 1 to 4 hours. The values of this final discriminant function were used in each patient to obtain the least-squares estimates of the intercept (a) and slope (b) as a function of time. This procedure was also used in 24 patients for the values of the final discriminant function based on arterial blood lactate, arterial blood lactate and partial pressure of carbon dioxide, and arterial blood lactate and stroke index. None of the mean slopes showed a significant difference between survivors and patients who died. Only the mean intercept of the final discriminant function based on arterial blood lactate and partial pressure of carbon dioxide reflected a significant difference. Inclusion of the trends of the final discriminant function did not provide significant additional predictive information. For this reason, no accumulative prognostic indexes were derived.

Nonlinear Prognostic Indexes

The discriminant functions listed in Table VI are all linear (additive) combinations of variables. Clinical experience has indicated that nonlinear combinations of data also may be useful. Such nonlinear combinations may be the products or ratios of certain variables, such as cardiac work, stroke work, peripheral vascular resistance and central blood volume (Table III). Among these, the final value of stroke work was the most reliable predictor of survival (Table IV). The relatively high level of reliability of this nonlinear combination motivated examination of other combinations of arterial pressure and blood flow. The formula, cardiac work = 13.6 × mean arterial pressure × cardiac output, was modified by using intraarterial systolic or diastolic pressure instead of mean arterial pressure, or cardiac index instead of cardiac output, or both. In addition to these modifications, six additional nonlinear combinations were obtained by dividing by heart rate. Among these combinations, intraarterial diastolic pressure × stroke index and intraarterial diastolic pressure × stroke volume, each provided the greatest reliability (85 percent), followed by mean arterial pressure × stroke index (83 percent). These combinations of pressure and flow measurements might be compared to stroke work = 13.6 × mean arterial pressure × stroke volume. However, they do not have specific physiologic designations, and their reliability is not significantly greater than that of the standard stroke work.

Discussion

In earlier studies in this unit on patients with acute myocardial infarction and shock, stroke index and intraarterial diastolic pressure provided the best combination of hemodynamic variables for predicting survival.[1] In a later study[2] on patients with drug overdose, an accumulative prognostic index was developed that took into account sequential changes in hemodynamic, metabolic and respiratory variables. In this study on an enlarged group of patients with myocardial infarction, selected metabolic, respiratory and renal variables were analyzed to determine whether they contribute to the information available from the hemodynamic variables alone. The sequential changes in these variables also were examined to determine whether an accumulative prognostic index could be developed for this group of patients.

Recent studies have suggested that measurements of pulmonary arterial wedge and left ventricular pressures may provide valuable prognostic information on the status of the left ventricle.[12–16] Measurements of these variables were available in several of the more recent patients, and the observations appear to indicate the value of such measurements. However, the data were not sufficient to warrant detailed statistical analysis. Among the hemodynamic variables measured in all patients, stroke index again emerged as the best single prognostic variable. Other measurements of flow, appearance time and mean circulation time also were more reliable than measurements of arterial pressure. When metabolic, respiratory and renal variables were included, arterial blood lactate emerged as the best individual prognostic variable. Urinary output was better than any single hemodynamic or respiratory variable. These findings are in contrast to those in patients with drug overdose, in whom measurements of arterial pressure were the most reliable followed by measurements of arterial pH and arterial blood lactate. In patients with drug overdose, measurements of blood flow were not significant predictors of survival.

The best prognostic indexes of survival in cardiogenic shock: The linear (additive) combination of arterial blood lactate with either partial pressure of carbon dioxide, stroke index or mean central venous pressure provided the greatest reliability in pre-

dicting survival in patients with myocardial infarction complicated by shock. The value of the partial pressure of carbon dioxide can be readily altered by changing the minute volume in a patient on a ventilator. For this reason, it may be preferable to use values of stroke index or mean central venous pressure in combination with those for arterial blood lactate. Among hemodynamic variables, the combination of stroke index and intraarterial diastolic pressure again provided the greatest reliability. In contrast to these findings, among patients with drug overdose, the combination of intraarterial systolic pressure with either arterial pH or arterial oxygen saturation produced the greatest reliability.

Another important difference between patients with myocardial infarction and those with drug overdose relates to the value of accumulative prognostic indexes. Whereas the accumulative prognostic index proved to be a valuable tool in the patients with drug overdose, it was not as helpful as the prognostic index based on only current values (momentary prognostic index) in patients with myocardial infarction and shock. The explanation for this lies in the different courses of the two groups of patients. In patients with drug overdose, the survivors and patients who died showed clearly divergent trends; among patients with myocardial infarction, there was no consistent trend in patients who died. However, the momentary prognostic index for patients with myocardial infarction does reflect the severity of the patient's condition and serves as a valuable prognostic indicator.

This prognostic index is derived solely from measured (continuous) variables. Inclusion of discrete variables, such as the clinical features listed in Table II, might be expected to improve reliability of such indexes.[17] For example, there were no survivors among patients with previous hypertension or congestive heart failure. Nevertheless, previous hypertension was not a significant factor in predicting survival in our group of 29 patients. This finding indicates the need for a larger number of patients when discrete variables are analyzed.

Although the linear (additive) discriminant function is usually the best predictive combination of variables, it is possible that some nonlinear combinations, such as those derived from products and ratios of variables, might provide greater reliability. For example, stroke work, which is a nonlinear combination of mean arterial pressure, cardiac output and heart rate, provides a high level of reliability. The nonlinear hemodynamic combinations that were considered did not yield a significant improvement over the linear combinations of hemodynamic variables in the reliability of predicting survival.

Depending on the availability of the measured variables, combinations of hemodynamic, respiratory and metabolic measurements may be selected to assess the patient's status at any given time. The prognostic indexes are given in Table VI. These indexes provide a basis for objectively evaluating the severity of a patient's illness before and after any given therapeutic intervention.

Mechanism and Significance of Widened QRS Complexes During Complete Atrioventricular Block in Acute Inferior Myocardial Infarction

K. I. LIE, MD,
HEIN J. WELLENS, MD, FACC
REINIER M. SCHUILENBURG, MD
DIRK DURRER, MD, FACC

Amsterdam, The Netherlands

Twelve of 35 consecutive patients admitted with complete atrioventricular (A–V) block complicating acute inferior myocardial infarction manifested widened QRS complexes. The escape beats had the pattern of left bundle branch block in four patients, right bundle branch block in five patients and both left and right bundle branch block in three patients.

His bundle recordings in five patients with escape beats that had a left bundle branch block configuration revealed a His bundle potential preceding the widened QRS complex at His–V intervals of 45 to 60 msec. Bradycardia-dependent left bundle branch block was demonstrated in two patients by His bundle pacing. In three patients the conducted beats had a left bundle branch block configuration after critical lengthening of the R–R interval during second degree A–V block before or after the episode of complete A–V block. In six patients whose escape beats had a right bundle branch block configuration, His bundle recordings did not reveal a His bundle potential preceding these beats.

Our observations suggest that widened QRS complexes with a left bundle branch block configuration could be due to an A–V junctional escape rhythm with phase 4 left bundle branch block. Alternatively in association with a right bundle branch block configuration it is possible that the widened QRS complexes represent a ventricular or fascicular escape rhythm.

Two of 12 patients with widened QRS complexes died. There were no significant differences in immediate mortality, 6 month mortality or mean peak serum glutamic oxaloacetic transaminase (SGOT) values between patients with narrow and widened QRS complexes. This finding suggests that widened QRS complexes during complete A–V block in acute inferior myocardial infarction have no prognostic significance.

Atrioventricular (A–V) conduction disturbances associated with acute inferior myocardial infarction are generally located in the A–V node when occlusion occurs proximal to the origin of the A–V nodal artery.[1-8] In 90 percent of cases this artery is a branch of the right coronary artery.[9] During complete A–V block the escape pacemaker below the site of block usually produces narrow QRS complexes.[1-8] Prolongation of QRS duration during complete A–V block in inferior myocardial infarction is considered to be of prognostic significance and to be associated with a high mortality rate.[6,7,10,11] It has been suggested that in these circumstances A–V block originates below the node.[12,13]

In this study we attempted to determine the frequency, prognostic significance, mechanism and site of origin of widened QRS complexes

11	73F	LBBB	0.16	60	nm	nm	Died 1st week
12	78M	RBBB	0.14	40	nH	40	Died 4th week

LBBB = left bundle branch block configuration; nH = QRS not preceded by His bundle potential; nm = HV interval not measured; NQRS = narrow QRS complexes in escape or conducted beats, or both; RBBB = right bundle branch block configuration; WQRS = widened QRS complexes in escape beats.

during complete A–V block in the setting of acute inferior myocardial infarction.

Material and Methods

The subjects were 225 patients admitted consecutively to the coronary care unit from February 1972 to July 1973 because of acute inferior myocardial infarction. All patients were admitted within 24 hours after the onset of symptoms, and the mean hospital arrival time was 4 hours. The diagnosis of acute infarction was based on a typical history of chest pain correlated with the appearance of diagnostic Q waves and characteristic serial changes in serum enzymes. In all patients with acute myocardial infarction, continuous electrocardiographic monitoring was performed. In several of these patients the electrocardiographic data were stored on magnetic tape. A 14 lead electrocardiogram with seven leads recorded simultaneously was obtained twice a day during the first 5 days, and additional electrograms were taken as necessary.

The location of infarction was defined according to the criteria of Lipman and Massie.[14] The group of patients with inferior infarction included those with the characteristics of diaphragmatic or posterior wall infarction (or both) with or without lateral wall involvement. The diagnosis of left and right bundle branch block was based on the criteria of the New York Heart Association.[15] High degree A–V block was defined as the presence of either second or third degree A–V block. Temporary pacing was instituted in high degree A–V block combined with cardiac failure, ventricular rates of less than 50/min or ventricular irritability.

In 8 of 12 patients with acute inferior myocardial infarction manifesting widened QRS complexes in the presence of complete A–V block, the sites of A–V block and escape mechanisms were studied by His bundle recordings. Informed consent was given by each of these patients. In one of the patients not catheterized, the widened QRS pattern has disappeared; diagnostic facilities were not available in the other three cases. During this procedure, three electrode catheters were passed through the femoral vein by the Seldinger technique. A tripolar electrode catheter was used to record the His bundle electrogram,[16] a bipolar catheter was positioned in the right ventricular apex for stimulation and a third unipolar catheter was used to record the intracavitary atrial complex. The site of block during complete A–V block was defined according to the criteria of Hecht and Kossmann.[17] The site was considered to be located in the A–V junction if, in the presence of a normal His–V interval, no P wave was followed by a His bundle potential. The A–V junction was defined to include the A–V node and the nonbranching part of the His bundle. Normal values for the His–V interval in our laboratory are 35 to 55 msec.

Two patients underwent stimulation of the His bundle. All eight patients were restudied by His bundle recordings, two during second degree A–V block and six after 1:1 A–V conduction had resumed. Four patients in the latter group were restudied at least 6 weeks after the onset of infarction. At that time the functional and effective refractory periods of the A–V node were also determined using the single test stimulus method during atrial pacing.[18]

Electrocardiographic leads I, II, III, V_1 and V_6, the unipolar intraatrial lead and the His bundle lead were recorded simultaneously, the latter with use of an Elema amplifier type EMT 12. The electrocardiograms were recorded on an eight channel high frequency direct-writing Elema recorder.

After discharge, all patients were followed up at intervals of 3 months. The significance of differences between mean peak values for serum glutamic oxaloacetic transaminase was tested by the Student *t* test. A chi square test was used to test the significance of differences in mortality rate.

Results

The hospital mortality rate in the 225 patients with acute inferior myocardial infarction was 11 percent. The mean age of all patients was 62 years, and

Mean Age, Mean Peak SGOT Values, Hospital and 6 Month Mortality Data of 35 Patients with A–V Block

	Patients (no.)	Mean Age (yr)	Mean Peak SGOT		Mortality	
			Units	Log*	Hospital	6 Months
Narrow QRS	23	63.2 (±9.4)	128	2.06 (±0.22)	5/23	1/15†
Widened QRS	12	68.2 (±6.7)	138	2.11 (±0.16)	2/12	0/10
P value		NS		NS	NS	NS

* For statistical analysis the logarithms of SGOT were used.

† These figures were related to patients who were followed up for at least 6 months.

Figures in parentheses indicate standard deviation; NS = not significant, $P < 0.10$; SGOT = serum glutamic oxaloacetic acid.

the mean peak value for SGOT was 97 international units (IU). Complete A–V block developed in 35 (15.5 percent) of the total group. The mean age of these patients was 65 years, and the mean peak value for SGOT was 132 IU. Seven (20 percent) of these 35 patients died in the hospital. Of the 25 survivors in this group who were followed up for at least 6 months, 1 patient died.

During complete A–V block, 12 patients (34 percent) manifested widened QRS complexes in escape beats (Table I). These beats had a configuration of left bundle branch block (four patients), right bundle branch block (five patients), or both (three patients).

The mean age of patients with widened QRS complexes in escape beats was 68 years and mean peak SGOT 138 IU . Two patients died of cardiogenic shock in the hospital. All 10 survivors, followed up for 6 to 17 months, are still alive. Statistically there were no significant differences in mean peak values for SGOT, immediate mortality or 6 month mortality rate between patients with widened and narrow QRS complexes in escape beats during complete A–V block (Table II).

Left Bundle Branch Block

In seven cases, escape beats with a left bundle branch block pattern were present during complete A–V block. Three of these seven patients also had left bundle branch block in conducted beats during second degree A–V block, before or after the episode of complete A–V block. Left bundle branch block in conducted beats occurred only after a critical lengthening of the R–R interval (Fig. 1). The duration of left bundle branch block ranged from 6 hours to 11 days. In six patients, left bundle branch block disappeared before 1:1 A–V conduction resumed, and in one patient (Case 5) left bundle branch block persisted for 6 days after the return to normal A–V conduction (Fig. 2).

His bundle recordings were obtained in five of the seven patients whose escape beats had a left bundle branch block configuration. In these patients, His

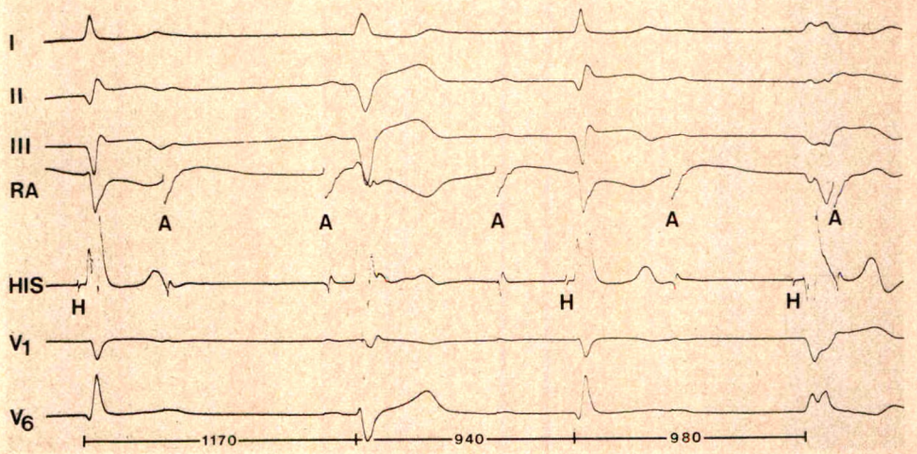

FIGURE 1. Case 4. Simultaneously recorded leads I, II, III, V_1, V_6, right atrial lead and His bundle lead. The first QRS complex is narrow and is preceded by a His bundle potential (H) at a His–V interval of 40 msec, thus indicating normal ventricular depolarization. The second QRS complex, which has a right bundle branch block configuration with left axis deviation, is not preceded by a His bundle potential, thus suggesting an origin in the inferior part of the left ventricle or near the posterior fascicle of the left bundle. The third QRS complex has all the characteristics of a nonaberrantly conducted beat. The last QRS complex shows a left bundle branch block configuration and is preceded by a His bundle potential at a His–V interval of 45 msec. As demonstrated by the intraventricular intervals, this represents a Wenckebach type of A–V conduction pattern with the development of left bundle branch block at a critical lengthening of the R–R interval. RA = right atrium.

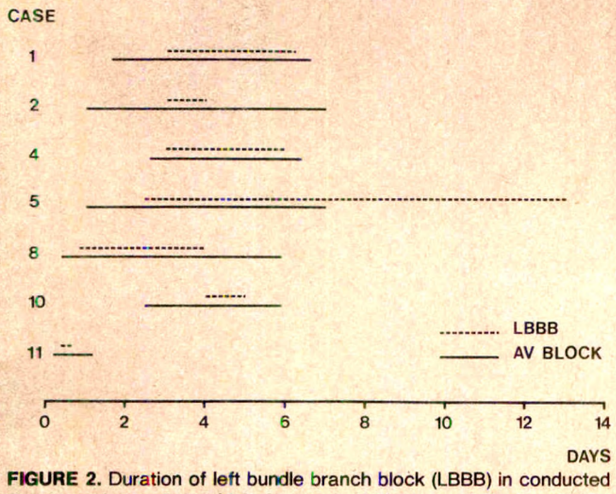

FIGURE 2. Duration of left bundle branch block (LBBB) in conducted or escape beats during high degree A–V block. In all seven patients left bundle branch block was preceded by A–V block. Left bundle branch block disappeared in six patients before 1:1 A–V conduction resumed. In one patient (Case 5) left bundle branch block persisted for 6 days after return of 1:1 A–V conduction.

bundle potentials were observed to occur 45, 45, 45, 50 and 60 msec, respectively, before the onset of the widened QRS complex. His–V intervals of escape beats with a left bundle branch block configuration were equal to those measured later in nonaberrantly conducted beats, except in one patient (Case 4) whose His–V interval was 5 msec shorter in the nonaberrantly conducted beats. In two patients pacing of the His bundle during complete A–V block revealed a bradycardia-dependent left bundle branch block (Fig. 3).

Four patients were restudied at least 6 weeks after infarction. In none of them could left bundle branch block be elicited, either at short premature beat intervals during atrial pacing or during escape beats occurring after carotid sinus massage or pacing at high rates. The functional and effective refractory period of the A–V node, as determined by the single test stimulus method during atrial pacing, was normal in three patients.

One patient (Case 1) manifested definite lengthening of the functional and effective refractory periods (600 and 510 msec, respectively, at a basic cycle length of 750 msec). At the time of restudy in the patient who previously showed a slightly prolonged His–V interval of 60 msec (Case 5) during complete A–V block in escape beats the His–V interval was still 60 msec, whereas A–V nodal conduction was normal as mentioned before. This finding suggests that temporary block within the His bundle was probably not responsible for this slightly prolonged His–V interval.

Right Bundle Branch Block

In eight patients the escape beats during complete A–V block showed a right bundle branch block configuration. The duration of appearance of these beats ranged from 4 hours to 2 days. In five of the six patients who had His bundle recordings, no His bundle activation could be recorded in or preceding the beats manifesting right bundle branch block. In one patient, the His bundle potential coincided with the beginning of the beats with a right bundle branch block configuration (Fig. 4); the latter had a QRS duration of 0.12 second and an indeterminate frontal QRS axis. In the other five patients, QRS duration ranged from 0.12 to 0.16 second, and all five patients manifested left axis deviation of the QRS complex in the frontal plane.

In all six patients with His bundle recordings, the escape beats with a right bundle branch block configuration occurred together with escape beats demonstrating narrow QRS complexes. The latter were all preceded by a His bundle potential occurring 40 to 50 msec before the QRS complex, thus indicating that the site of A–V block was located in the A–V junction. Escape beats with a right bundle branch block configuration occurred at a rate of 40 to 60/min. This

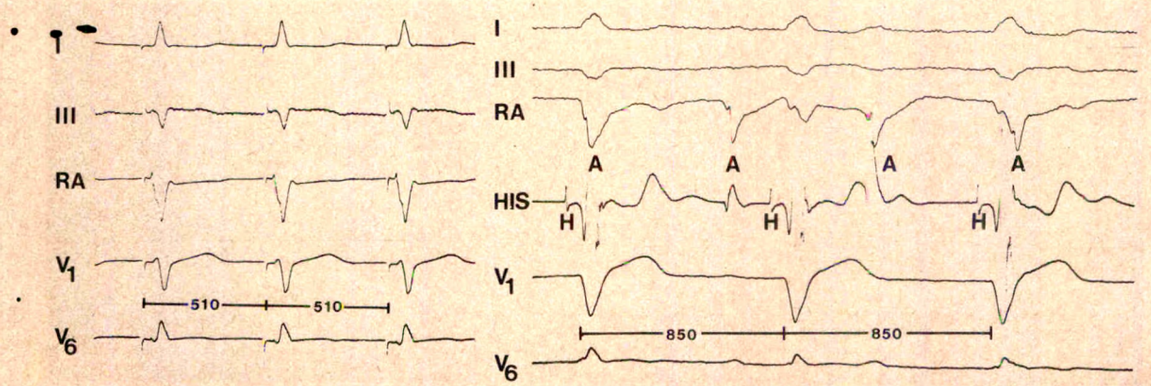

FIGURE 3. Case 5. Pacing of the His bundle revealing bradycardia-dependent left bundle branch block. **Right,** during third degree A–V block the escape beats showing a left bundle branch block configuration are preceded by a His bundle potential (H) at a His–V interval of 60 msec. **On the left,** during pacing of the His bundle, left bundle branch block disappeared at driving rates of 510 msec or less, thus indicating bradycardia-dependent left bundle branch block. Note that the interval between the stimulus artifact and onset of the QRS complex is identical to the His–V interval on the right, thus excluding the possibility that slowing of conduction in the right bundle branch was responsible for normalization of the QRS complex. RA = right atrium.

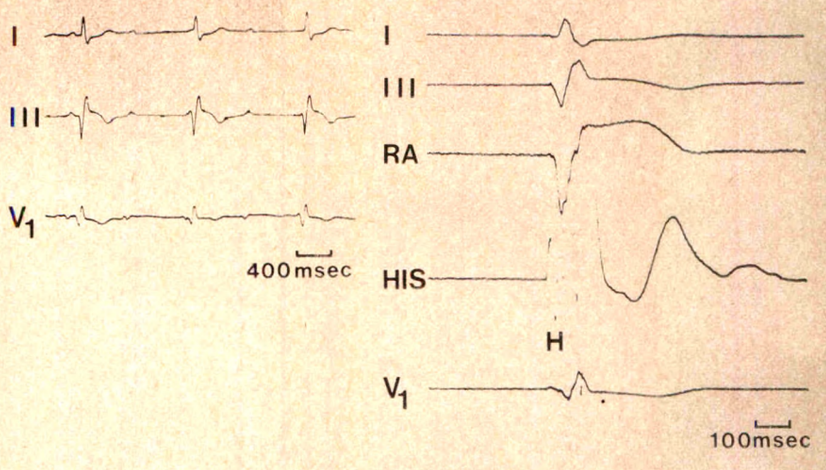

FIGURE 4. Case 1. Escape beats showing right bundle branch block configuration with an indeterminate frontal QRS axis and a QRS duration of 0.12 second during third degree A–V block **(left). On the right,** the His bundle potential (H) coincides with the onset of the escape beat with a right bundle branch block configuration, thus suggesting an origin near or in the main stem of the left bundle.

rhythm alternated with the A–V junctional escape rhythm. In three patients the frequency of the escape beats with a right bundle branch configuration was higher than that of the A–V junctional escape beats with narrow QRS complexes. In three other patients the right bundle branch block escape rhythm had a lower frequency than the A–V junctional rhythm and appeared in the presence of an unstable A–V junctional mechanism.

Discussion

Pick[19] recently listed the following six potential mechanisms for aberration of escape beats:

1. "Preferential" A–V path
2. Phase 4 depolarization
3. Ventricular (fascicular) origin
4. Functional dissociation within a bundle branch
5. Wedensky facilitation
6. Supernormality of intraventricular conduction

As he pointed out, the first and last three mechanisms are hypothetical and may apply only exceptionally.

Singer et al.[20] demonstrated diastolic phase 4 depolarization in Purkinje cells leading to aberration of late impulses. Rosenbaum et al.[21] pointed to the combination of hypopolarization and spontaneous diastolic depolarization in one of the bundle branches leading to bundle branch block. They called this phase 4 block and found coronary artery disease in most of their patients with this phenomenon.

Our electrocardiographic observations in patients with left bundle branch block are in accordance with the criteria of bradycardia-dependent bundle branch block of Massumi.[22] Sarachek[23] and Gay and Brown[24] were the first to mention the presence of bradycardia-dependent bundle branch block during high degree A–V block in inferior myocardial infarction. However, His bundle recordings are necessary to determine the site of origin of escape beats with widened QRS complexes.

A case of bradycardia-dependent bundle branch block associated with inferior myocardial infarction was described first by Bauer et al.[25] in 1965. In that case (their Patient 13) left bundle branch block occurred during sinus bradycardia. In contrast, in our group left bundle branch block occurred exclusively during high degree A–V block; before A–V block six patients manifested sinus bradycardia without left bundle branch block even at ventricular rates slower than those present during A–V block (Fig. 5). In our series of 225 patients with inferior myocardial infarction none of the 35 with sinus bradycardia (defined as a sinus rate of less than 60/min) manifested bradycardia-dependent left bundle branch block during conducted beats. We therefore assume that simultaneously occurring ischemia of the A–V junction and main stem of the left bundle was responsible for block in the A–V junction and also for phase 4 block in the left bundle branch.

We do not understand why in our patients phase 4 block always occurred in the left bundle branch. We know of no data suggesting that the slope of phase 4 depolarization is steeper in the left than in the right bundle branch.

Anatomic basis for bundle branch block in inferior infarction: Sutton and Davies,[4] reporting on 11 patients with complete heart block associated with inferior myocardial infarction, correlated the patho-

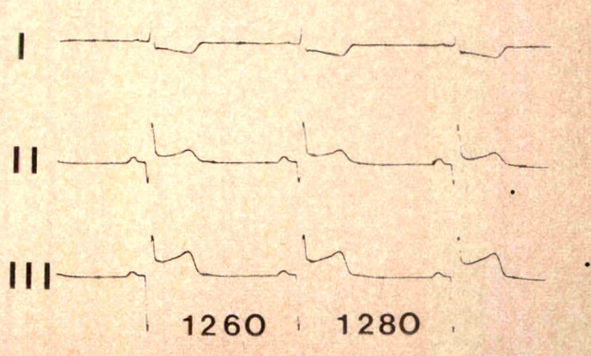

FIGURE 5. Case 4 (see Fig. 1). Electrocardiogram during sinus bradycardia with a ventricular rate lower than that in Figure 1. No left bundle branch block occurs.

logic data with the electrocardiographic findings. They found no constant relation between the presence of bundle branch block during A–V block in inferior myocardial infarction and structural damage in the bundle branches, and they considered the occurrence of bundle branch block during A–V block in inferior myocardial infarction to be related to reversible ischemia rather than to structural damage. The coincidence of left bundle branch block and high degree A–V block during the acute phase of inferior myocardial infarction suggests that a common anatomic factor is responsible for this association.

Frink and James[26] postulated two anatomic mechanisms for widened QRS complexes during A–V block in inferior myocardial infarction: (1) two vessel disease, involving both the right coronary artery and the descending branch of the left coronary artery, and (2) vascularization of the His bundle and proximal part of the bundle branches occurring exclusively through the A–V nodal artery. Since only one of our patients had a previous anterior infarction and since both left bundle branch block and A–V block were transient in the other patients, our findings seem to be more compatible with the second mechanism.

His bundle electrograms—conduction mechanisms: Our electrocardiographic observations with His bundle recordings in six patients with escape beats demonstrating a right bundle branch block configuration indicated that these beats originated below the A–V junction. In one patient (Case 1) the His bundle potential coincided with the beginning of the QRS complex with a right bundle branch block configuration, a duration of 0.12 second and an indeterminate frontal QRS axis. These findings suggest that the site of origin of this beat could be in or near the main stem of the left bundle. This type of escape beat has been described previously by Massumi and co-workers.[27]

During the electrocardiographic observations in the other five patients who had escape beats with a right bundle branch block configuration and a QRS duration of 0.12 to 0.16 second, no His bundle potential could be recorded near the beginning of the QRS complex with a right bundle branch block configuration. Since these beats demonstrated left axis deviation, their origin in the inferior part of the left ventricle or near the posterior fascicle of the left bundle seems likely. The rather high frequency (50 to 60/min) of these escape beats with a right bundle branch block configuration in six patients and the observation that in three patients the beats with a right bundle branch block pattern dominated the A–V junctional escape rhythm are suggestive of an active mechanism of impulse formation in the left ventricle. These last mechanisms are also reported in accelerated ventricular rhythms during sinus bradycardia or the slow phase of sinus arrhythmia.[28]

Our studies suggest that widening of the QRS complex of the escape pacemaker may be due either to an A–V junctional escape mechanism with phase 4 bundle branch block (which occurred in the left bundle branch in all of our patients), or to an escape rhythm located in the left ventricle, alternating with the A–V junctional pacemaker. The A–V block was situated in the A–V junction in all of our patients studied by His bundle recordings who showed widened QRS complexes in escape beats during complete A–V block in inferior myocardial infarction.

Both widening of the QRS complex and A–V block regressed within a few days. There were no significant differences in immediate mortality, 6 month mortality or mean peak values for SGOT between patients with narrow and widened QRS complexes, thus suggesting that widened QRS complexes during complete A–V block in inferior myocardial infarction have no prognostic significance.

Platelet Survival in Patients with Prosthetic Heart Valves

R. KENNETH STUART, MD, FRCP (C)

London, Ontario, Canada

Chromium-51 platelet survival studies were carried out in 20 patients with a prosthetic heart valve. Only 1 of 10 patients with a prosthetic mitral valve had a significantly shortened platelet survival time, and the mean value of 8.3 ± 0.96 (±1 standard deviation) days was not significantly different from that of normal control subjects (8.9 ± 0.75 days). Four of 10 patients with an aortic prosthesis had a shortened platelet survival time, and the mean value of 7.8 ± 0.10 days in this group differed significantly from the normal control value ($P < 0.05$). Treatment with aspirin did not appear to alter platelet survival but, when combined with Coumadin therapy, resulted in marked prolongation of bleeding time. Our results do not support the concept that thrombus formation on the prosthesis is the cause of the shortened platelet survival time since thrombus formation is more likely to occur in mitral than aortic prostheses. Reduced platelet survival time secondary to damage by the prosthesis, similar to the problem of hemolysis in red blood cells, is a more likely explanation.

Thrombus formation on a prosthetic heart valve with subsequent embolization continues to be one of the serious complications occurring after the initial postoperative period in patients undergoing valve replacement. The frequency of this complication has differed with the valve design, with various modifications of a given valve type and also with the site of the valve, (mitral vs. aortic).[1–4] However, the trend has been toward a reduced frequency of embolic complications with the more recent valve prostheses.[1,3,5] It is thought that the process of thrombus formation on prosthetic surfaces may be primarily related to the adherence of platelets with subsequent buildup of platelet aggregates and the deposition of fibrin.[6,7] Inherent in this theory is the concept that drugs of the "antiplatelet" type might be capable of decreasing both thrombus development and subsequent embolization.[7–9] The latter has now been shown by Sullivan et al.[9,10] to be true for patients with prosthetic heart valves. Shortened platelet survival times have also been demonstrated in patients with prosthetic heart valves, as initially reported by Lander et al.[11] and confirmed by Weily and Genton[12] and Harker and Slichter[13] in larger series. Preliminary results of studies from this laboratory[14] of platelet survival in patients with prosthetic valves did not appear to agree with the observations in the latter two reports. In this report we present further data from the analysis of findings in 20 patients.

Methods

Patients: One hundred and fourteen consecutive patients with prosthetic heart valves, assigned randomly to a double-blind trial of aspirin, 300 mg daily, are being followed up at regular intervals. Twenty of these patients, selected only on the basis of living close enough to the hospital to permit daily collection of blood samples, underwent platelet survival studies. All patients were receiving sodium warfarin (Coumadin®) therapy.

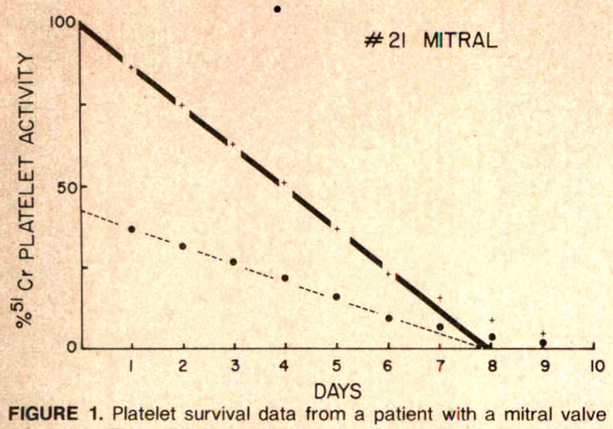

FIGURE 1. Platelet survival data from a patient with a mitral valve prosthesis. The **solid dots** represent the observed chromium-51 activity as a percent of the total ^{51}Cr platelet activity. The data from the first 6 days were used in a linear regression equation to find a theoretical 100 percent activity for day zero. The ^{51}Cr platelet activity remaining on each day was then expressed as a percent of this value (+'s). The regression line was also extrapolated to zero percent activity to find the platelet survival time in days.

Platelet survival studies: Chromium-51–labeled platelet survival studies were carried out according to the method of Aster and Jandl.[15]

Platelet aggregation: Platelet aggregation was studied by a modification of the turbidometric method described by Born,[16] using a Payton Aggregometer system (Payton Associates Limited, Scarborough, Ontario, Canada). All blood for platelet testing was collected and handled in plastic materials. Platelet-rich plasma was prepared by collecting whole blood in 3.8 percent sodium citrate, followed by centrifugation at 260 g for 10 minutes. The aggregation response to collagen and adrenalin was tested.

Platelet counts: Platelets were counted by phase contrast microscopy according to the method of Brecher and Cronkite.[17]

Prothrombin times: Quick one-stage determinations of prothrombin times were performed, using Simplastin, as described by the manufacturer (Warner-Chilcott Laboratories, Morris Plains, N. J.).

Bleeding times: Bleeding times were measured in all patients, using the modified Ivy-Template method, as described by Mielke et al.[18]

Platelet aggregation studies and determinations of prothrombin and bleeding times were performed at regular intervals in these patients; the results reported here were obtained within a month of the time of the platelet survival study.

Results

Ten of the 20 patients had received a prosthetic aortic valve and 10 a prosthetic mitral valve. Data concerning the time of the platelet survival study and type of prosthetic valves are shown in Table I.

Platelet survival studies: Figure 1 shows the platelet survival data from a patient with a prosthetic mitral valve. To remove as much bias as possible from the interpretation of data, the percent of remaining ^{51}Cr activity on each of the first 6 days was substituted into a linear regression equation and the line extrapolated to zero activity to find the platelet survival time in days. The pattern of ^{51}Cr disappearance was linear, and any tailing off over the last few days, as seen in Figure 1, involved less than 10 percent of the initial activity and a negligible population of platelets. The mean platelet survival time for six normal control subjects was 8.9 ± 0.75 (1 standard deviation [SD]) days (Table II). For the patients with a mitral valve prosthesis, the mean platelet survival time was 8.3 days, which was not statistically different from that of the normal subjects. However, the mean platelet survival time for the 10 patients with a prosthetic aortic valve was 7.8 days, which was significantly shorter than that of the normal subjects ($P < 0.05$). Analysis of the individual platelet survival times reveals that 4 of 10 patients in the aortic valve group had a platelet survival time more than 2 standard deviations shorter than the mean value of the control subjects (6.3, 6.3, 7.1 and 7.3 days, respectively), whereas only 1 of the 10 patients with a mitral valve prosthesis had a significantly shortened platelet survival time (6.9 days). The difference in frequency of shortened platelet survival times between patients in the mitral and aortic valve groups was significant ($P < 0.05$). The platelet survival times of all patients receiving aspirin did not differ significantly

Placebo	8.1 ± 1.3	16.7 ± 0.28	8.3 ± 3.0	1/9

* Prothrombin time ratio = patients' prothrombin time in seconds divided by the control time.

from the values for all patients receiving placebo. Similarly, no differences due to aspirin treatment were noted within the mitral valve group alone or the aortic valve group alone (Table III).

The size of the prosthesis did not correlate with platelet survival time. Of the four patients in the aortic valve group with a shortened platelet survival time, two had Starr-Edwards no. 9, and two had a Starr-Edwards no. 10 valve. The remaining six Starr-Edwards aortic valves were also size 9 or 10, except for one no. 8. The platelet survival time was 9.2 days in the patient with the latter valve.

Platelet counts: At the time of the platelet survival study, 18 of the 20 patients had a platelet count of 188,000 to 400,000/mm^3 (mean 241,000; normal range 150,000 to 400,000/mm^3). Platelet counts performed at 3 month follow-up visits, both before and after the platelet survival study, tended to be quite constant for any individual patient with a maximal range of 100,000 and no tendency to either rise or fall with time. Two of the 20 patients had slightly decreased platelet counts of 129,000/mm^3 and 125,000/mm^3, respectively, with platelet survival times of 7.9 and 7.3 days. Their platelet counts before and after the survival time did not vary by more than 10,000/mm^3. Of the five patients with short platelet survival times, one had a low count (125,000/mm^3) and the others a normal count (180,000, 240,000, 310,000 and 340,000/mm^3).

Prothrombin times: To produce a single figure for analysis, each patient's prothrombin time was divided by the control time and expressed as a ratio (Table IV). No significant differences were noted between patients with mitral and aortic valve prostheses or between those treated by aspirin and placebo. The "prothrombin time ratios" for the five patients with a shortened survival time were 1.3, 1.6, 1.4, 1.2 and 1.4, respectively (mean 1.4). This mean value differed statistically from the mean of the remaining patients (1.8; $P < 0.01$).

Bleeding times: Patients receiving aspirin had a significantly longer bleeding time than those receiving placebo ($P < 0.05$; Table IV).

Platelet aggregation: Aggregation results are reported as the number of patients demonstrating the inhibiting effect of aspirin, as evidenced by the lack of a second phase in response to adrenaline and a significantly diminished response to collagen. With the exception of one patient in the placebo group whose platelet aggregation was inhibited, the patients' aggregation curves were as expected, inhibited in the aspirin group and normal in the placebo group.

Discussion

Lander et al.[11] demonstrated slightly shortened platelet survival times in two of five patients with a prosthetic mitral valve and in one of two patients with a prosthetic aortic valve. Weily and Genton[12] reported reduced platelet survival times in 15 of 16 patients with a prosthetic mitral valve. The shortening to a mean of 5.49 days was significant when compared with 6.73 days for normal control subjects ($P < 0.001$). Harker and Slichter[13] demonstrated marked shortening in patients with mitral (5.2 days) and aortic (6.5 days) valve prostheses compared with findings in normal subjects (9.5 days). The small difference between the two patient groups was significant. In our study, the platelet survival time was within normal limits in 9 of 10 patients with a prosthetic mitral valve and 6 of 10 with a prosthetic aortic valve. The mean platelet survival time for patients with a mitral valve prosthesis of 8.3 days was not significantly different from that of normal subjects (8.9 days), but that for patients in the aortic valve group (7.8 days) was significantly shortened. These results differ from the findings previously cited in that the shortening of platelet survival time was generally less frequent and less marked. In addition, the shortening appeared to be more a feature of aortic than of mitral valve prostheses.

No correlation between bleeding and platelet survival times could be demonstrated despite the markedly prolonged bleeding time in the aspirin-treated patients (Table IV). The prolongation of the bleeding time was greater than one would expect from administration of aspirin only in a dose of 300 mg daily.[18] Similarly, Coumadin alone in doses sufficient to achieve a therapeutic level of anticoagulation does not significantly prolong bleeding time,[19] and our patients receiving Coumadin alone had a normal bleed-

ing time (placebo group, Table IV). These results, which suggest that the observed prolongation of bleeding time is a result of a combined effect of aspirin and Coumadin on the hemostatic mechanism, are in agreement with the findings of O'Reilly et al.[19] The platelet counts in our patients were in the normal range except for a slight reduction in two patients (125,000 and 129,000/mm^3) and, as in the study by Harker and Slichter,[13] there was no correlation with the platelet survival time.

Platelet aggregation studies (Table IV) confirmed that aspirin-treated patients were obtaining the desired inhibitory effect on "in vitro" platelet tests. The studies also provided evidence of drug compliance in both the aspirin- and placebo-treated groups. This "in vitro" evidence, together with the prolonged bleeding time as "in vivo" evidence, does suggest that platelet function was being inhibited by treatment with aspirin. No effect of aspirin on platelet survival was demonstrated although the degree of shortening was so small that any beneficial drug effect would be difficult to observe.

The prothrombin time results appear to bear some relation to platelet survival time. The mean prothrombin time for the five patients with a shortened platelet survival time was significantly different from that of the remaining patients. However, the mean for all patients in the aortic and mitral valve groups differed with respect to platelet survival time but did not differ with respect to prothrombin time. Harker and Slichter[13] did not observe any effect of prothrombin time on platelet survival.

No relation was noted between the size of the prosthetic valve and platelet survival time. Harker and Slichter[13] did find a correlation between the nonendothelialized surface area and platelet destruction.

Relation to clinical thromboembolic episodes: Harker and Slichter[13] concluded that platelets may undergo destruction through thrombus formation on prosthetic valves and that the best indicator of this occurrence is a shortened platelet survival time. Their hypothesis would explain the greater degree of shortening in patients in the mitral valve group since they have a greater frequency of thromboembolic complications. Weily and Genton[12] concluded that platelet abnormalities regularly occur in patients with a mitral valve prosthesis and that these abnormalities may contribute to thromboembolism. They considered platelet survival time a more sensitive measure of altered platelet kinetics than platelet adhesiveness or aggregation. The rate of occurrence of embolic complications in our study was similar to that of other reports. Three definite episodes have been reported in 58 patients with a prosthetic aortic valve (5 percent) and five episodes in 35 patients with a mitral valve prosthesis (14 percent). On the other hand, platelet survival times were normal in all but 1 of the 10 patients in our mitral valve group but were shortened in 4 of the 10 in our aortic valve group. This observation casts some doubt on the hypothesis that shortened platelet survival is related to the development of thrombotic material on a valve and subsequent embolization.

A possible explanation for the difference observed in the prevalence and severity of shortened platelet survival in our study may lie in the valve design. Eight of the 10 aortic valves, and 5 of the 10 mitral valves were of the Starr-Edwards type, and all were of the more recent cloth-covered design. Embolic complications are less frequent with these newer valves.[1,3,5] Thus, if the assumption is correct that a decreased tendency to thrombus formation and subsequent embolization will be associated with normal platelet survival time, then a higher percentage of patients with a normal platelet survival time would be expected with the more recent valve designs. Weily et al.[20] recently reported normal platelet survival time in six of nine patients with a Beall mitral valve prosthesis.

Aortic vs. mitral valve prosthesis: The explanation just given would not account for the greater prevalence and severity of the shortened platelet survival times in the patients with an aortic rather than a mitral valve prosthesis. An alternative hypothesis is that platelets undergo more damage in passing over the aortic valve region where the flow rates and pressures are considerably greater than they are in the region of the mitral valve. This increased damage may be comparable to the increased frequency of significant hemolysis in association with aortic valve prostheses.

Encephalogenic Cardiomyopathy After Stimulation of the Brain Stem in Monkeys

HSING I. CHEN, MD

Repeated electrical stimulation of the brain stem including the hypothalamus, pons and medulla in monkeys produced an increase in arterial blood pressure, cardiac arrhythmias, various degrees of S–T segment or T wave changes and structural damage to the myocardium. The following ultrastructural changes in the myocardium occurred: distension of sarcoplasmic reticulum, swelling of mitochondria, disarrangement of filamentous arrays, formation of contraction bands, dissociation of intercalated discs and focal necrosis. These changes are similar to those found in ischemic myocardial tissue and myocardial necrosis induced by catecholamines. The myocardial lesions are probably related to activation of the sympathetic mechanism in the brain stem.

Electrocardiographic changes simulating myocardial ischemia have been well documented in patients with cerebrovascular accidents, head injury and other intracranial disorders.[1–7] However, positive findings of myocardial lesions have not been consistently reported at autopsy.[1,3,4,6,7] Comparatively few experimental investigations have been performed to correlate electrocardiographic changes induced by irritation of the central nervous system with possible myocardial lesions. Porter et al.[8] observed no histologic evidence of myocardial damage in cats after stimulation of the hippocampus and amygdala, in spite of sustained electrocardiographic abnormalities. Burch et al.[9] produced myocardial lesions in mice by injection of blood into the cranium, but electrocardiography was not performed. Eichbaum et al.[10,11] studied electrocardiographic changes in dogs and guinea pigs after head trauma or an increase in intracranial pressure, but did not examine the myocardium microscopically. Melville et al.[12] succeeded in producing myocardial damage in some but not all cats displaying cardiac arrhythmias and ST–T changes after prolonged electrical stimulation of the pressor areas of the hypothalamus. Greenhoot and Reichenbach[13] have reported a high frequency of myocardial damage and electrocardiographic abnormalities both in patients with subarachnoid hemorrhage and in cats after electrical stimulation of the midbrain pressor areas.

In this investigation in monkeys we attempted to study the electrocardiographic changes and the fine structural alterations of the myocardium after electrical stimulation of the brain stem, and to determine which specific sites, when stimulated, are associated with cardiac damage.

Methods

Recording of electrocardiogram and blood pressure: Ten monkeys (Macaca cyclopis) of either sex, weighing 5 to 7 kg, were lightly anesthetized with sodium pentobarbital, 25 to 30 mg/kg injected intraperitoneally. The trachea was intubated to assure free ventilation. The femoral artery was cannulated and the arterial blood pressure monitored with a Statham P23AC

FIGURE 2. Monkey 3. Changes in blood pressure (BP), heart rate (HR) and electrocardiogram induced by stimulation of the tegmentum of the lower pons. Stimulations (**heavy bars** between blood pressure and heart rate tracings) were repeated 46 times at intervals of 10 to 15 minutes. The electrocardiogram, taken at the time as marked on the signals (a to j) of the slow speed tracings, is shown in the **right panels. Top tracing** depicts the changes induced by the first stimulation. Note the increased blood pressure (102 mm Hg) and sinus bradycardia during stimulation (b), and the poststimulatory cardiac arrhythmias (nodal rhythm, bidirectional and multifocal ventricular ectopic beats) (c, d). The arrhythmias persisted for 55 seconds. Note also the slight S–T depression after the rhythm had converted to normal (e). **Middle tracing** depicts changes induced by the fifth stimulation. Note the similar arrhythmias and the more marked S–T depression (f, g). **Bottom tracing** shows changes induced by the final (46th) stimulation. Note the poststimulatory ventricular tachycardia (i) and the prominent S–T depression (j).

transducer. Heart rate was monitored with a Grass 5P4 tachometer which was triggered by the arterial pulses. These recordings were made on a Grass 5D polygraph. The electrocardiogram was monitored with a Hewlett Packard 1500A recorder.

Application of electrical stimulation: The head of the animal was fixed in a David-Kopf stereotaxic instrument, and the desired areas of the brain were located and stimulated with a unipolar electrode (outer diameter 0.6 mm). Stimulation was provided by a Grass S4 rectangular pulse generator coupled with an isolation unit. The parameters for stimulation were 50 Hz, 2 msec and 5 to 12 v. Each stimulation lasted 15 to 35 seconds. The stimulation was repeated 5 to 10 minutes after the electrocardiogram demonstrated reversion to sinus rhythm. In each experiment, except for one in which a single stimulation produced cardiac arrhythmias lasting 57 minutes, the stimulations were repeated 15 to 46 times. Stimulations were repeated until the total duration of cardiac arrhythmias had reached 25 minutes or more, or until the electrocardiogram had shown a definite change in the S–T segment or T wave, or both.

Examination of the myocardium: At the end of the experiment, the chest was opened and the heart removed from the anesthetized animal. Myocardial tissue was taken immediately from the left ventricular wall and interventricular septum. For light microscopy, the tissue was fixed in 10 percent formalin, embedded in paraffin, sectioned and stained with hematoxylin-eosin. A conventional histochemical technique for succinic dehydrogenase activity was performed using frozen sections.[14] Preparation for electron microscopy consisted of double fixation in 3 percent buffered glutaraldehyde and 1 percent osmium tetroxide with Millonig's buffer, and embedding in epon 812.[15] Sections were cut on a Porter Blum MT-1 ultramicrotome, double-stained with uranyl acetate and lead citrate, and examined with a Hitachi HU-11E microscope.

TABLE I

Electrocardiographic Changes in 10 Monkeys After Electrical Stimulation of the Brain

Monkey no.	Stimulation: Site	Stimulation: Times of Repetition	Elevation of Blood Pressure (mm Hg)	Electrocardiographic Changes	Sum Duration of Cardiac Arrhythmias (min)
1	Posterior hypothalamus	38	47	Sinus tachycardia, bigeminal VPCs, VT, marked S–T depression	21
2	Left tegmentum of lower pons	40	56	Bigeminal VPCs, nodal rhythm, slight S–T elevation, increased T wave amplitude	25
3	Right tegmentum of lower pons	46	102	Sinus bradycardia, nodal rhythm, bidirectional & multifocal VPCs, VT, marked S–T depression	28
4	Left dorsolateral upper medulla	1	46	Sinus bradycardia with atrioventricular block, bigeminal & multifocal VPCs, VT, marked S–T elevation	57
5	Right dorsolateral mid-medulla	15	54	Sinus bradycardia (initial), sinus tachycardia (late), slightly increased T wave amplitude	—
6	Midline of ventral lower medulla	39	44	Nodal rhythm, intermittent & multifocal VPCs, supraventricular tachycardia, increased T wave amplitude	24
7	Right ventrolateral lower medulla	21	59	Slight sinus tachycardia, slight S–T depression	—
8	Parietal lobe	40	—	No remarkable changes	—
9	Thalamus	38	—	No remarkable changes	—
10	Midline of mid-medulla	35	66	No remarkable changes	—

VPCs = ventricular premature contractions; VT = ventricular tachycardia.

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

Localization of stimulation sites of the brain: The brain was perfused with normal saline solution followed by 10 percent formalin in saline solution, and then fixed in 10 percent formalin for several days. Brain sections, 40 μ in thickness, were cut using a cryostat and then stained with Weil's method. The sites of electrical stimulation were traced from the electrode tract and diagrammed as shown in Figure 1. They were distributed as follows: posterior hypothalamus (Monkey 1), tegmentum of lower pons (Monkeys 2 and 3), dorsolateral reticular formation of upper medulla (Monkey 4), dorsolateral portion of mid-medulla (Monkey 5), ventral portion of lower medulla (Monkeys 6 and 7), parietal lobe (Monkey 8), thalamus (Monkey 9) and mid-medulla (Monkey 10).

Results

Changes in electrocardiogram and blood pressure: Table I summarizes the changes in the electrocardiogram and blood pressure in the 10 animals after stimulation of the brain. Stimulation of the parietal lobe and the thalamus in the two control animals (Monkeys 8 and 9) produced no significant changes. Stimulation of the brain stem including the hypothalamus, pons and medulla consistently evoked an increase in blood pressure ranging from 44 to 102 mm Hg. Electrocardiographic changes simulating myocardial ischemia (elevation of S–T segment or increased amplitude of the T wave, or both) were observed in all but one animal (Monkey 10). The changes usually occurred after the first stimulation. They were mild and transient at first, but became progressively more prominent and persistent upon repeated stimulations. Monkeys 5 and 7 manifested only slight sinus tachycardia or bradycardia, or both. Other animals displayed profound cardiac arrhythmias including nodal rhythm, various forms of ventricular premature contractions and ventricular tachycardia. Figure 2 shows a typical example of these changes. The ectopic beats usually persisted for 10 to 55 seconds and then returned to sinus rhythm unless repeated stimulation was given. In one excep-

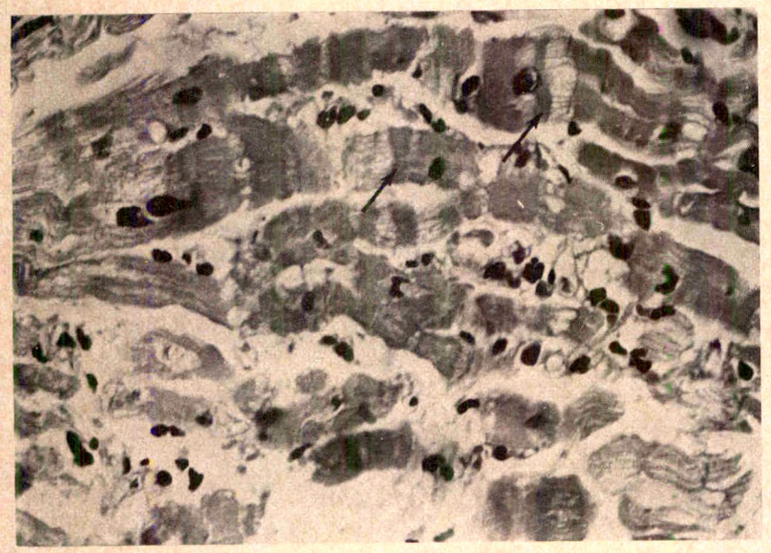

FIGURE 3. Monkey 4. Section of myocardium. Note the contraction bands of myofibers **(arrows)** associated with necrosis of individual muscle fibers. (Hematoxylin-eosin ×600, reduced by 32 percent.)

tional animal (Monkey 4), a single stimulation triggered ventricular extrasystoles for 57 minutes.

Light microscopic findings: The seven animals (Monkeys 1 to 7) displaying S–T segment or T wave changes, or both, upon electrical stimulation of the brain stem all showed scattered and isolated patches of myocardial damage in the ventricular wall and interventricular septum without noticeable gross changes. The severity of the myocardial lesions ranged from hyalinization of muscle fibers to complete myocytolysis and, more frequently, foci of necrotic myocytes with widened interstitial spaces containing fibroblasts and macrophages at the subendocardial region (Fig. 3). In some areas the myofibers were overcontracted and exhibited coarse, coalescent transverse or oblique bands or more intense eosinophilic-stained material (Fig. 3). Degenerative changes were not found in the three monkeys (Monkeys 8 to 10) that had no significant electrocardiographic changes.

Histochemical findings: The myocardium of the seven monkeys with electrocardiographic changes and myocardial damage demonstrated by light microscopy all showed an uneven pattern of succinic dehydrogenase activity (Fig. 4). This was characterized by areas of increased enzymatic activity at the borders of the clear zones, which represent the intercalated discs. The distance between the discs was markedly shortened. In the other three monkeys with no abnormal electrocardiographic findings, the succinic dehydrogenase activity in the myocardium was homogeneously and evenly distributed.

Electron microscopic findings: The two control animals (Monkeys 8 and 9) stimulated at the parietal lobe and the thalamus had a normal electrocardiogram and normal appearance of the fine structures of the myocardium. The appearance conformed in general to previous descriptions of normal mammalian myocardium.[16,17] The myofibers were moderately contracted with regular periodic bands. Mitochon-

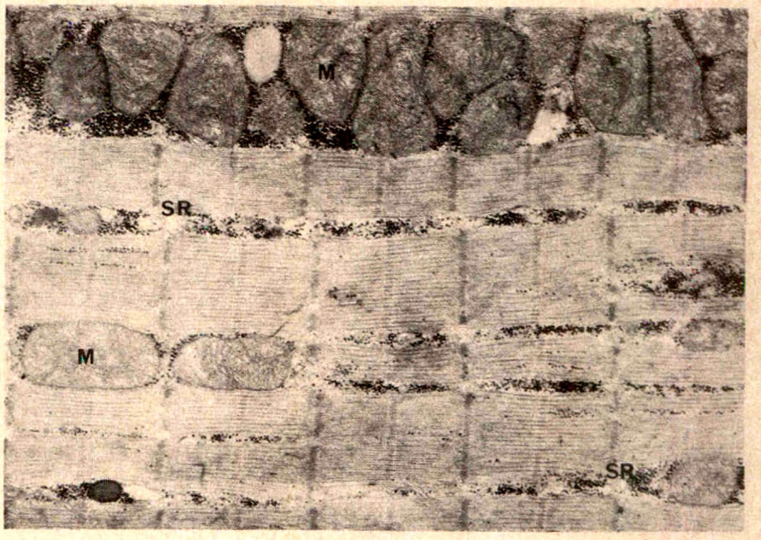

FIGURE 5. Monkey 8. Electron microscopic section of myocardium. Note the moderately contracted myofibrils, the normal mitochondria (M) and sarcoplasmic reticulum (SR). (×22,500, reduced by 36 percent.)

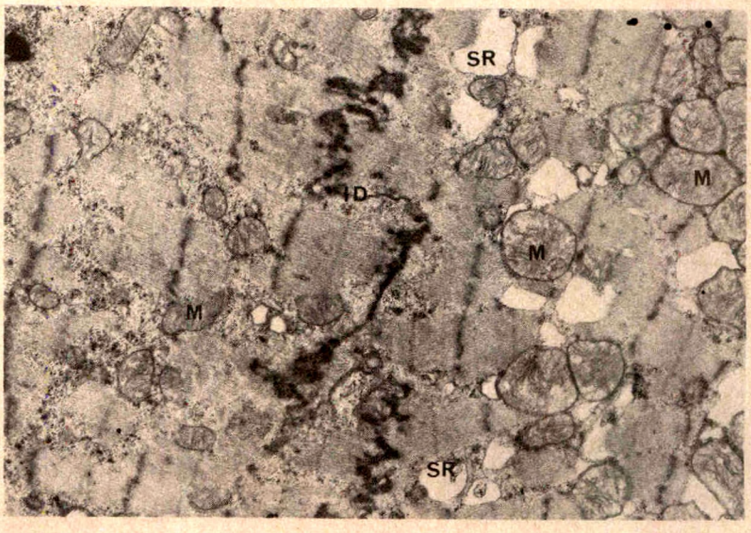

FIGURE 6. Monkey 1. Myocardium showing portions of two myofibers as demarcated by an unduly marked intercalated disc (ID). Note that the myofiber on one side contains swollen mitochondria (M), distended sarcoplasmic reticulum (SR) and tubular system. Glycogen granules are scant. On the other side, the mitochondria are scarce and shrunken and glycogen particles abundant. (×13,250, reduced by 36 percent.)

dria were normal, and glycogen particles and occasional lipid droplets were present among the myofibrils (Fig. 5).

In animals displaying slight electrocardiographic changes after stimulation at the dorsolateral mid-medulla (Monkey 5), ventrolateral lower medulla (Monkey 7) and midline area of mid-medulla (Monkey 10), there were mild degenerative changes with preservation of the intracellular organelle relations. Only the sarcoplasmic reticulum and transverse tubular system occasionally appeared prominent and dilated.

The five animals (Monkeys 1 to 4 and 6) that manifested cardiac arrhythmias associated with ST–T changes upon stimulation of the brain stem had severe ultrastructural abnormalities of the myocardium. Degenerative and necrotic changes of myofibers were readily demonstrated in many tissue blocks, especially those from the subendocardial region. These changes closely simulated those induced by injection of sympathomimetic amines[18–22] and those observed in the early stage of myocardial ischemia.[16,23] A number of myofibers showed distended sarcoplasmic reticulum and swollen mitochondria. In some sections two neighboring myofibers demarcated by an intercalated disc displayed different degrees of damage (Fig. 6). The intercalated discs showed an increased electron density. The structure of sarcomeres were indistinct. In longitudinal sections typical dense contraction bands were present throughout (Fig. 7). At each end of the contraction bands the relatively intact sarcomeres were overstretched and the intercalated disc at one end was torn apart (Fig. 7). Mitochondria were trapped in the contraction bands and were degenerating. In the more advanced instances, many foci of necrosis were observed within the myocytes. The necrosis was unrelated to the intercalated discs and often extended across the latter. In the necrotic myocytes there were broken and fused myofibrils and degenerated and disorganized mitochondria

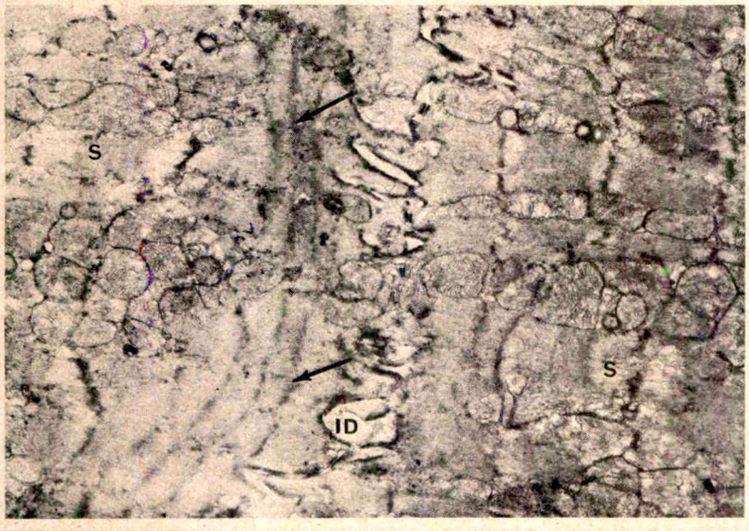

FIGURE 7. Monkey 4. Myocardium showing contraction bands of actin and myosin filaments **(arrows)** in damaged myofibers. Note also the overstretched sarcomeres (S) and separated intercalated disc (ID) at both sides of the contraction bands. (×13,250, reduced by 36 percent.)

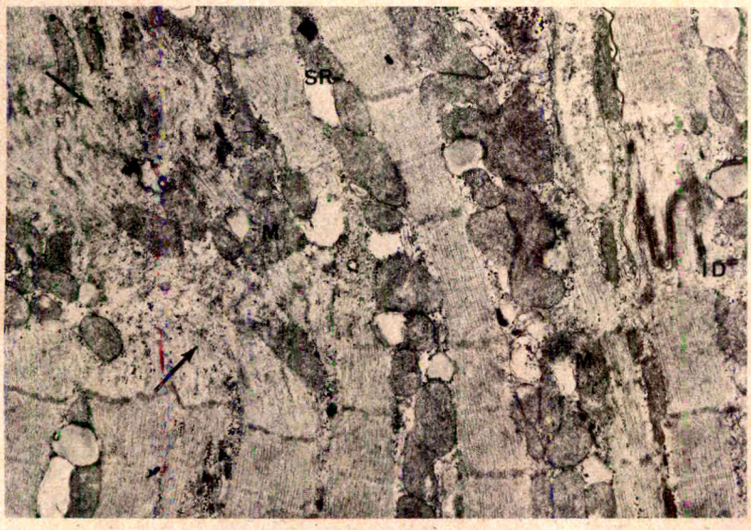

FIGURE 8. Monkey 6. Myocardium showing focal myocytolysis. Note destruction of sarcomeres **(arrows)**, degeneration of mitochondria (M) and distension of sarcoplasmic reticulum (SR). (×13,250, reduced by 36 percent.)

associated with fat droplets (Fig. 8). The nuclei showed margination and clumping of chromatin granules along nuclear membrane with rarefied nucleoplasm.

Discussion

Mechanism of myocardial damage after brain stem stimulation: Our investigation shows that stimulation of the brain stem in monkeys can produce myocardial damage in association with hypertension, cardiac arrhythmias and ST–T abnormalities. We found that stimulation not only of the hypothalamus[12,24] and midbrain,[13] but also of the pons and medulla, can produce these changes. The development of myocardial damage depended greatly on which site in the brain was stimulated. A single electrical stimulation of the dorsolateral reticular formation of the upper medulla (Monkey 4) elicited marked vasomotor reactions, prolonged cardiac arrhythmias, profound S–T segment elevation and considerable structural damage to the myocardial fibers, as demonstrated by both light and electron microscopy. Stimulation of the hypothalamus, pons and other areas of the medulla produced similar changes in the electrocardiogram and blood pressure and similar myocardial damage. Repeated stimulation of the thalamus and the parietal lobe evoked no significant cardiovascular or myocardial changes. Because the thalamus and parietal lobe have little autonomic function, this observation suggests that the autonomic nervous system is involved in the production of myocardial lesions. Increased sympathetic discharge after stimulation of the brain stem may release norepinephrine from the nerve ending in the heart and result in the production of myocardial damage. Similar changes have been produced after stimulation of the stellate ganglia[25] or parenteral injection of sympathomimetic amines such as epinephrine, norepinephrine and isoproterenol.[18–22] In these studies, focal myocardial lesions were produced which were similar to those found in our experiment. In patients with various intracranial disorders[1,4,6,7] and in experimental intracranial hemorrhage,[9] myocardial lesions were not always found, possibly because the appropriate areas of the brain were not consistently involved or stimulated. In addition, the early myocardial lesions produced by coronary occlusion[16] and injection of sympathomimetic agents[18,20,21] are reversible in nature[23,26] and, in patients who die of intracranial disease, sometimes are completely abolished before death.

Our findings suggest that physiologic and structural changes of the myocardium are both relevant to early ischemia. The mitochondrial abnormalities shown histochemically are characteristic of early ischemic or hypoxic injury,[9,27,28] as are the fine structural changes of mitochondria and sarcoplasmic reticulum. Coronary arterial constriction[24] and increased myocardial oxygen requirement[29] by local release of norepinephrine could mediate the myocardial ischemic lesions associated with ST–T segment alterations we observed in the experimental animals. The strongly contracted myofibrils seen occasionally in myocytes may indicate an immediate effect of catecholamines on the contractile elements since similar abnormalities have been produced in animals 6 to 10 minutes after injection of isoproterenol.[18]

Role of cardiac arrhythmias: In our studies, myocardial damage was more severe in monkeys that had marked cardiac arrhythmias. We believe that cardiac arrhythmias may contribute to myocardial damage by reducing the efficiency of cardiac function and impairing blood supply to the myocardium. However, two animals that had ST–T alterations with only slight changes in sinus rate and no ectopic beats had fine structural lesions in the myocardium. This finding is in agreement with the observations of Melville et al.[24] and indicates that this type of myocardial damage can occur in the absence of arrhythmias.

Other neurohumeral mechanisms: Other mechanisms of myocardial damage in these experiments seem unlikely. Anesthesia and experimental preparations in the control animals that underwent stimulation of the thalamus and parietal lobe were not accompanied by physiologic or morphologic cardiac changes. Also, there was little to suggest morphologically that the damage was related to adrenal cortical secretion or electrolyte disturbance. Corticosteroids and phosphate can produce striking mitochondrial changes with calcium deposition in the matrix,[30] but we did not observe these alterations. Myocardial damage can also be produced after stimulation of the midbrain in animals that have undergone adrenalectomy.[13] Potassium deficiency produces slackened myofibrils, severe cellular edema and sometimes myofibrilar destruction and necrosis.[31] These findings were not quite similar to those observed in our experiments. Patients with stroke or head injury who manifested electrocardiographic changes suggesting myocardial ischemia did not have electrolyte imbalance.[6,7] However, further studies will be required to elucidate the ultimate neurohumoral mechanism involved in the pathogenesis of encephalogenic cardiomyopathy.

Reflex Inhibitory Effects of Vagal Afferents in Experimental Myocardial Infarction

PAUL KEZDI, MD, FACC
R. KARL KORDENAT, MS
SARDA N. MISRA, MD

Dayton, Ohio

In experimental myocardial infarction with hypotension, low output state and shock (produced by injection of 0.2 ml of metallic mercury into the circumflex coronary artery of closed chest anesthetized dogs) serial recordings were made of postganglionic sympathetic and aortic baroreceptor nerve activity in addition to cardiac output, mean blood pressure, electrocardiogram and heart rate. With the decrease in cardiac output and mean blood pressure after injection of mercury, aortic nerve activity decreased as expected but, contrary to expectations, postganglionic sympathetic nerve activity also decreased. It was postulated that this decrease was due to a powerful cardiac vagal afferent reflex that could override the compensatory increase of sympathetic activity usually present with systemic baroreceptor withdrawal. Cutting or blocking the vagus nerves resulted in an immediate increase in sympathetic nerve activity followed by increases in cardiac output, mean systemic blood pressure and aortic nerve activity. Atropine, although it increased heart rate, did not reproduce the effect of vagotomy on sympathetic activity and cardiac output.

Recent renewed interest in the role of vagal afferents originating in the heart, primarily in the left ventricle and left atrium, has stimulated a number of investigators to study the reflex functions of the cardiac baroreceptors in myocardial infarction and cardiogenic shock. Several studies[1–7] have shown that in experimental coronary artery occlusion and myocardial infarction vagally mediated depressor reflexes may be present and increased activity from vagal afferent nerves originating in the left ventricle can be demonstrated. Other studies[8–12] have not confirmed the existence of depressor reflexes originating in the left ventricle during experimental coronary occlusion.

The problem has clinical importance because marked bradycardia and hypotension are common complications of myocardial infarction in man, particularly in the early phase. Some investigators[13,14] have suggested that the low cardiac output in patients with such complications is due, in addition to impaired cardiac pump function, to inadequate venous return.[13,14] However, many patients may also have a lack of adequate compensatory increase in systemic flow resistance despite the decreased cardiac output and hypotension,[15,16] thus indicating a depressor mechanism that may be partially responsible for the decreased cardiac output, inadequate distribution of blood flow and change in compensatory resistance.

The somewhat conflicting results in experimental myocardial infarction are perhaps due to different techniques used in producing coronary artery occlusion or myocardial infarction, or both, and to the different types of preparations used to study the reflex. It is well known that thoracotomy in open chest preparations used in many of the reported studies results in an increase in heart size that may tend to decrease the responsiveness of left ventricular baroreceptors. FIGURE 1. Changes in mean blood pressure and cardiac output after 3 hours of hypotension and shock and subsequent disruption of vagal trunks in seven dogs **(left graphs)** and response to atropine (0.1 mg/kg) in five animals with shock. Thirty minutes after atropine vagal trunks were severed **(right graphs).** Horizontal bars are standard deviations of means. *P* values indicate significance of differences between previous state and the state below which the *P* value is shown. Where no value is shown the difference was not significant.

sequent experimental coronary occlusion may not result in the same reflex effects as occlusion in a closed chest preparation. In addition, opening of the pericardium may also change ventricular receptor response, and isolation of the anterior descending coronary artery for placing an occluding cuff may destroy afferent nerve fibers originating in the ventricle. Frink and James[17] have shown that the fibers mediating the vagal reflex are located beside the anterior descending and main left coronary arteries in the dog.

To eliminate some of these objections with the open chest preparation, we decided to restudy this problem in the closed chest animal using a previously described technique of selective coronary artery catheterization and production of myocardial infarction with cardiogenic shock.[18] We have previously reported our studies of the hemodynamic changes resulting from the extensive myocardial infarction and shock using this technique in 68 closed chest animals.[19,20] In this report we present our studies on the effect of vagal afferents on heart rate, cardiac output, mean systemic blood pressure and renal postganglionic sympathetic discharge during the development of decreased cardiac output and hypotension using our closed chest technique of experimental myocardial infarction. Atropine was given to evaluate its effectiveness in blocking this vagal inhibitory reflex. The reflex was subsequently interrupted by cutting both vagal trunks while leaving the systemic baroreceptors (aortic and carotid sinus) intact. Our results indicate that vagal afferents, especially those originating in the left ventricle, probably play a role in the prolonged depression of cardiac output, mean systemic blood pressure and sympathetic activity in cardiogenic shock.

Method

Twelve mongrel dogs of both sexes were used for these experiments. The animals were anesthetized with alpha chloralose (60 to 80 mg/kg body weight) and urethan (40 mg/kg). The neck was opened by midline incision and both vagus nerves were isolated high in the neck. The sheath of the vagus was split just below the junction with the superi-

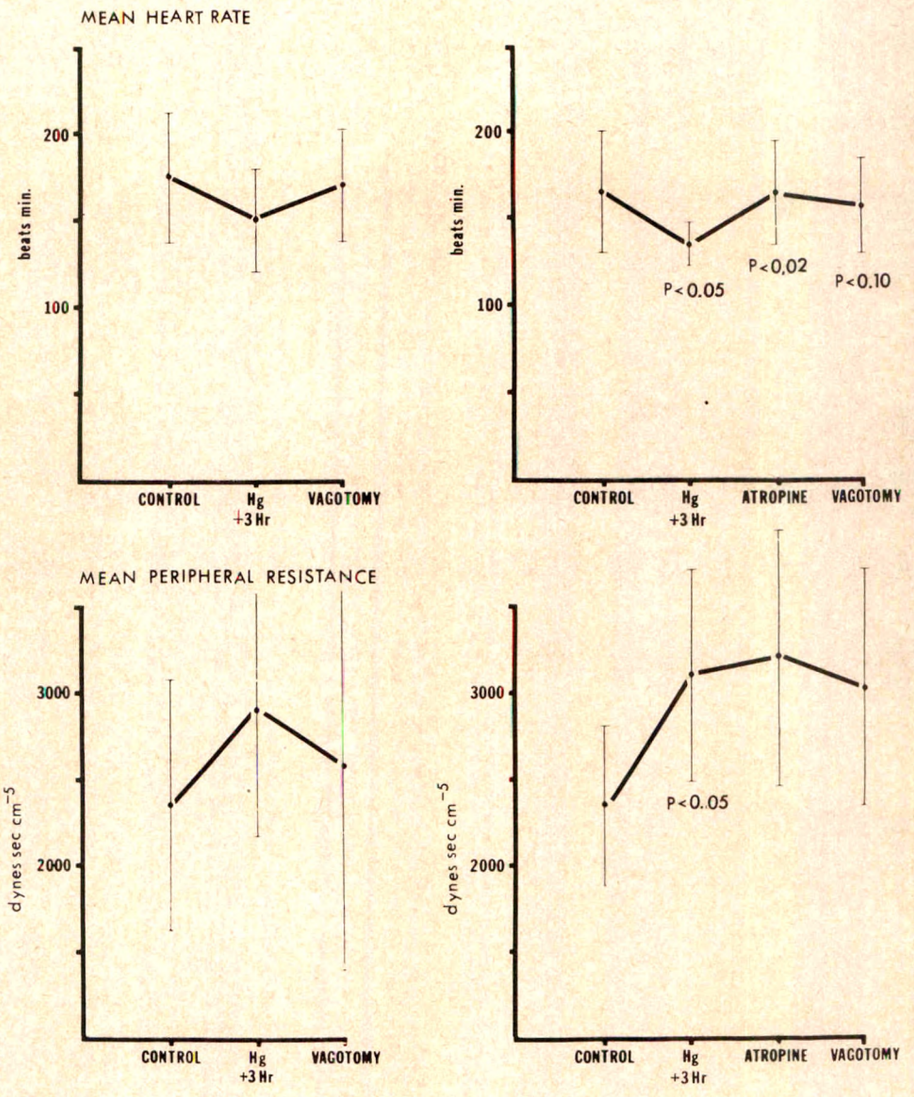

FIGURE 2. Changes in heart rate and peripheral arteriolar resistance in the same seven dogs as in Figure 1.

or laryngeal nerve, and the aortic nerves were carefully isolated on both sides. The aortic nerves were identified by placing them loosely on platinum bipolar electrodes and recording characteristic action potentials. These nerves were not disrupted and care was taken not to damage them. After identification they were immersed in mineral oil. The left carotid artery was dissected and a double catheter was introduced for probing the left coronary artery as previously described.[18] For the recording of postganglionic sympathetic activity, the left kidney was isolated retroperitoneally and postganglionic sympathetic fibers to the kidney were isolated. In two experiments recordings from sympathetic nerve fibers to the spleen were also obtained. The nerve chosen for recording was crushed peripherally by hemostat and was placed on bipolar platinum-iridium electrodes. The entire field was immersed in mineral oil warmed to body temperature. A catheter was advanced through the isolated femoral vein into the right atrium for the injection of dye.

Base-line recordings: For recording of aortic and sympathetic nerve activity, Tektronix 122 preamplifiers were used which were connected to Astrodata amplifiers. For the sympathetic nerve recordings a band pass filter of 80 to 1,000 cycles/sec and for the aortic nerve recordings 80 to 10,000 cycles/sec was used. The recordings were followed visually on the oscilloscope, and nerve activity was identified also by audio technique and then permanent recordings were made by a Honeywell 1507 Visicorder. Sympathetic and aortic nerve activity was quantified by rectifying of the recorded signal, feeding the data into an integrator and using a meaning circuit with a 3 second time constant. Blood pressure was recorded through the carotid artery catheter, the tip of which was in the ascending aorta. Heart rate was calculated from the time interval between the upstrokes of the systolic pressure waves. Cardiac output determinations were performed in duplicate using 2.5 mg indocyanine green dye for each injection through the venous catheter into the right atrium and withdrawing blood by Harvard constant withdrawal pump through a Gilford densitometer. Calculation of cardiac output was performed by the triangulation technique and the results were compared with those obtained simultaneously with a Lexington cardiac output computer. The average of the two sequential cardiac outputs was used in the calculation of the results.

Production of myocardial infarction: Base-line recordings of pressures, aortic and sympathetic nerve activi-

ty, cardiac output and the electrocardiogram were performed in each animal before myocardial infarction was produced. The inner catheter was then advanced into the outer catheter which had previously been passed through the left common carotid artery into the ascending aorta. Under image intensifier the left coronary ostium was entered with the outer catheter. By advancing the inner catheter and injecting small amounts of contrast dye (Hypaque-M®, 75%), it was possible to advance the inner catheter into the circumflex coronary artery as previously described.[18] When the inner catheter was in location, 0.2 ml of metallic mercury was injected through the catheter under image intensifier control into the circumflex coronary artery. The injection was followed by a flush with 1 ml of physiologic saline solution. The inner catheter was then withdrawn and the outer catheter placed into the ascending aorta for later recording of blood pressure and cardiac output. This technique, a modified version of the method of Lluch et al.,[21] was used to produce myocardial infarction in more than 60 previous experiments.[19,20] In those experiments approximately 80 percent of the animals had severe myocardial infarction with shock and low cardiac output within 1 to 4 hours.

Recordings of cardiac output, blood pressure, sympathetic and aortic nerve activity were repeated every 30 minutes after signs of myocardial infarction appeared in the electrocardiogram after the injection of mercury. The nerves were not moved from the electrodes and the animals were kept warm with use of a heating pad during this time. Fluid was replaced by slow infusion of dextrose in saline solution. Repeated small doses of the anesthetic were given as needed.

When cardiac output decreased to approximately 50 percent of control level and blood pressure decreased significantly, which usually occurred within 3 hours after mercury injection, the following interventions were made. In the first group of seven dogs (Group 1), the isolated vagus nerve high in the neck was cut on both sides without cutting the aortic nerves, which had previously been separated from the vagus. In a second group of five dogs (Group 2), atropine was given intravenously (0.1 mg/kg) before the vagus nerves were cut. Recordings were repeated after administration of atropine. Thirty minutes after injection of atropine, the vagus trunks were cut in these animals as in the previous group. All data were calculated as averages of means, and the base-line measurements before infarction were compared with measurements obtained after infarction, after vagotomy alone and after atropine and vagotomy, using each animal as its own control. For statistical analysis of the differences between experimental states (base-line, infarction, infarction plus vagotomy or atropine) the paired *t* test of Snedecor was used.

Results

Cardiac output and arterial blood pressure: Cardiac output and mean systemic blood pressure decreased in both groups of animals after injection of mercury into the circumflex coronary artery as was shown in previous experiments (Fig. 1). The decrease reached about 50 percent of the base-line value 3 hours after injection of mercury. Calculated peripheral resistance simultaneously increased but the increase was less than that expected from the decrease of cardiac output since mean systemic blood pressure also decreased (Fig. 2). Heart rate generally decreased and was 16 percent below control level at 3 hours. However, these changes reached statistical significance only in Group 2 (atropine plus vagotomy). Table I shows the average hemodynamic changes in all experiments.

Aortic nerve activity, sympathetic discharge and cardiac vagal afferent activity: With the decrease in cardiac output and systemic blood pressure, the mean aortic nerve activity also decreased in both groups as expected. But contrary to the expected reflex response under normal physiologic conditions, sympathetic discharge to the kidney was decreased to about 50 percent of the base-line activity despite the baroreceptor withdrawal (Fig. 3 and 4). Since baroreceptor input to the cardiovascular centers from the aortic nerve (and presumably the carotid sinus nerves) was markedly decreased, as shown by the decrease of aortic nerve activity, inhibition of sympathetic drive must have originated in other areas of the cardiovascular system, presumably in the heart itself. This powerful reflex was transmitted through vagal afferents since, when the vagus nerves were cut bilaterally high in the neck (leaving the aortic and carotid sinus nerves intact), there was an immediate increase of mean sympathetic activity in both groups which persisted until termination of the experiment 1 hour after the disruption of the vagus nerves (Fig. 3 and 4). Simultaneously with the increased sympathetic activity, cardiac output and systemic mean blood pressure also increased (Fig. 1). However, the increase reached significance for cardiac output only in Group 1 (vagotomy only) and for blood pressure in Group 2 (atropine plus vagotomy). The change in mean heart rate after cutting the vagus was not significant. Calculated peripheral resistance showed a tendency to decrease, but did not change significantly. Aortic nerve activity increased, reflecting the increase in systemic blood pressure, but this increase did not suffice to inhibit the increased sympathetic drive when the powerful cardiac vagal afferent activity was interrupted.

The responses of renal and splenic sympathetic fiber activity did not differ when compared in the two experiments in which both were recorded. Renal and splenic nerve activity levels were equally suppressed during shock and equally raised after the vagus was cut. However, the number of comparison recordings was insufficient to make a definite determination.

Effect of atropine: In the experiments in which atropine was given intravenously before the vagus was cut, mean sympathetic nerve activity, cardiac output and systemic blood pressure did not increase after administration of atropine, but heart rate significantly increased. (Fig. 1 and 4). When the vagus was subsequently cut bilaterally in these atropinized animals an increase in mean sympathetic nerve activity occurred as well as an increase in cardiac output and systemic blood pressure, thus indicating that atropine blocked only the efferent vagal activity responsible for bradycardia but did not block the central sympathetic inhibition of the afferent vagal reflex originating in the heart. Thus, atropine may have

eliminated the vagal efferent component of bradycardia but did not change cardiac performance or redistribution of blood flow. Since the heart rates before and after mercury injection were relatively high, the effect of atropine was also only modest.

Discussion

Considerable evidence has been collected by investigators in recent years that vagal afferents may play a role in the suppressed cardiac function and systemic circulation in certain cardiovascular diseases. Mark et al.[22] have shown in patients with aortic stenosis that syncope after effort may be due to a vagal afferent reflex resulting from distension of the left ventricle. Exercise in patients with aortic stenosis resulted in peripheral venous dilatation rather than constriction, probably as a result of the excessive stimulation of the vagal afferents in the left ventricle. Experimental evidence seemed to substantiate the results in patients.[23] In other experiments using the isolated hind limb preparation with constant flow, Hanley et al.[24] demonstrated that myocardial infarction resulted in decreased rather than increased perfusion pressure as would be expected from the decrease of systemic blood pressure and cardiac output in this condition. The renal vascular bed also showed vasodilatation according to Hanley et al.,[25] and Gorfinkel et al.[26] found only moderate decrease of renal blood flow and production of urine.

Sympathetic and vagal activity after myocardial infarction and effect of vagal block: In our experiments the decrease of sympathetic activity was shown by actual recording of electroneurograms simultaneously with the withdrawal of baroreceptor input demonstrated by reduced aortic nerve activity. Cardiac output and blood pressure decreased simultaneously. The decrease in pressure occurred despite the increase in calculated peripheral resistance. However, the increase in resistance probably does not reflect the state of the peripheral blood vessels. First, some of the increase in resistance is perhaps due to increased circulating catecholamines originating in the adrenal medulla as occurs in myocardial infarction.[27,28] Second, there is probably poor organ perfusion due to the reduced cross-sectional area of the resistance vessels caused by sludging and marked decrease of velocity of circulation through the peripheral vascular system. Thus, peripheral resistance is increased despite decreased central sympathetic drive to the vascular system.

The disruption of the inhibitory reflex originating in the heart results in an increased sympathetic

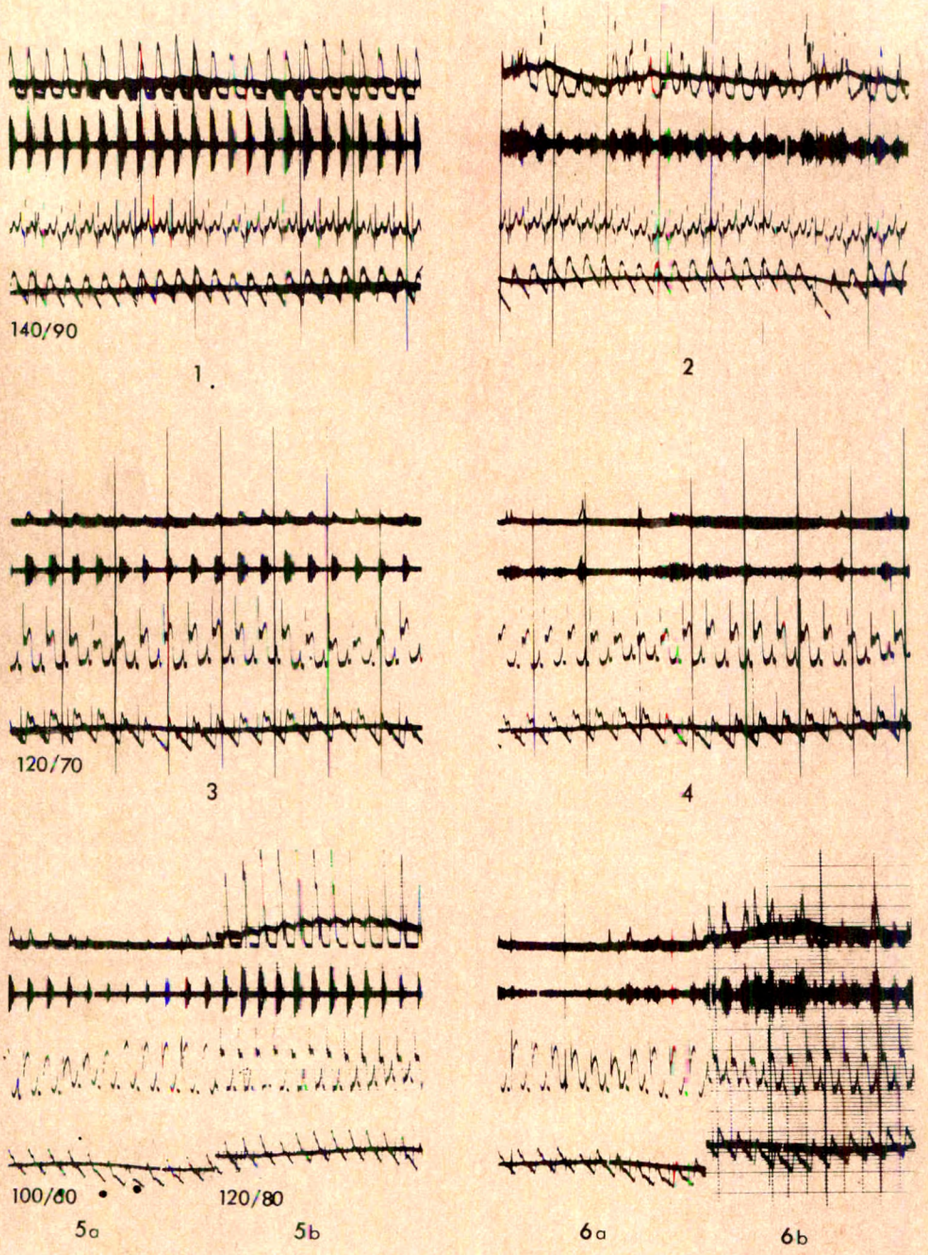

FIGURE 3. Example of aortic nerve **(left panels 1, 3, 5a and 5b)** and postganglionic sympathetic nerve **(right panels 2, 4, 6a and 6b)** activity in one dog before **(panels 1 and 2)** and after 3 hours of myocardial infarction with hypotension and low cardiac output **(panels 3 and 4),** and before **(5a and 6a)** and after **(5b and 6b)** bilateral vagotomy during the 4th hour of shock. In each panel the graphs from bottom to top indicate systemic blood pressure (straight line is mean pressure), electrocardiogram, actual nerve recording, integrated nerve activity (straight line is mean activity). Note the decrease in aortic and sympathetic nerve activity at 3 and 4 hours **(panels 3, 4, 5a and 6a)** and increased activity after vagotomy **(panels 5b and 6b).**

drive, as we could see in our experiments, leading to an increase of cardiac output and probably raising the peripheral pressure above the critical closing pressure in many vascular areas.[29,30] This finding indicates that the vagal afferent reflex actually functions in a reverse manner in myocardial infarction, thereby leading to hypotension, decreased cardiac output and bradycardia and, in some degree, defeats the pressor regulating system by its positive feedback mechanism. With the advance of time the peripheral effects of sludging and slowing of the circulation are so overwhelming that cardiac performance further deteriorates, probably in part because of metabolic depressant factors, and all attempts to improve circulation are of no avail.[31] We have shown in these experiments that, within 3 hours from the onset of myocardial infarction, blocking the vagus or cutting it leads to temporary improvement of cardiac output and probably improvement of the circulation to critical organs. Atropine does not duplicate the effect of vagus block in spite of its effect on heart rate.

Renal blood flow is maintained despite hypotension in coronary occlusion.[25] There is probably a difference in the circulatory adjustment of different vascular beds and their sympathetic drive in shock. However, this may apply more to the sympathetic response to elimination of baroreceptor inhibition than to maximal inhibition itself. Kendrick et al.[32] have

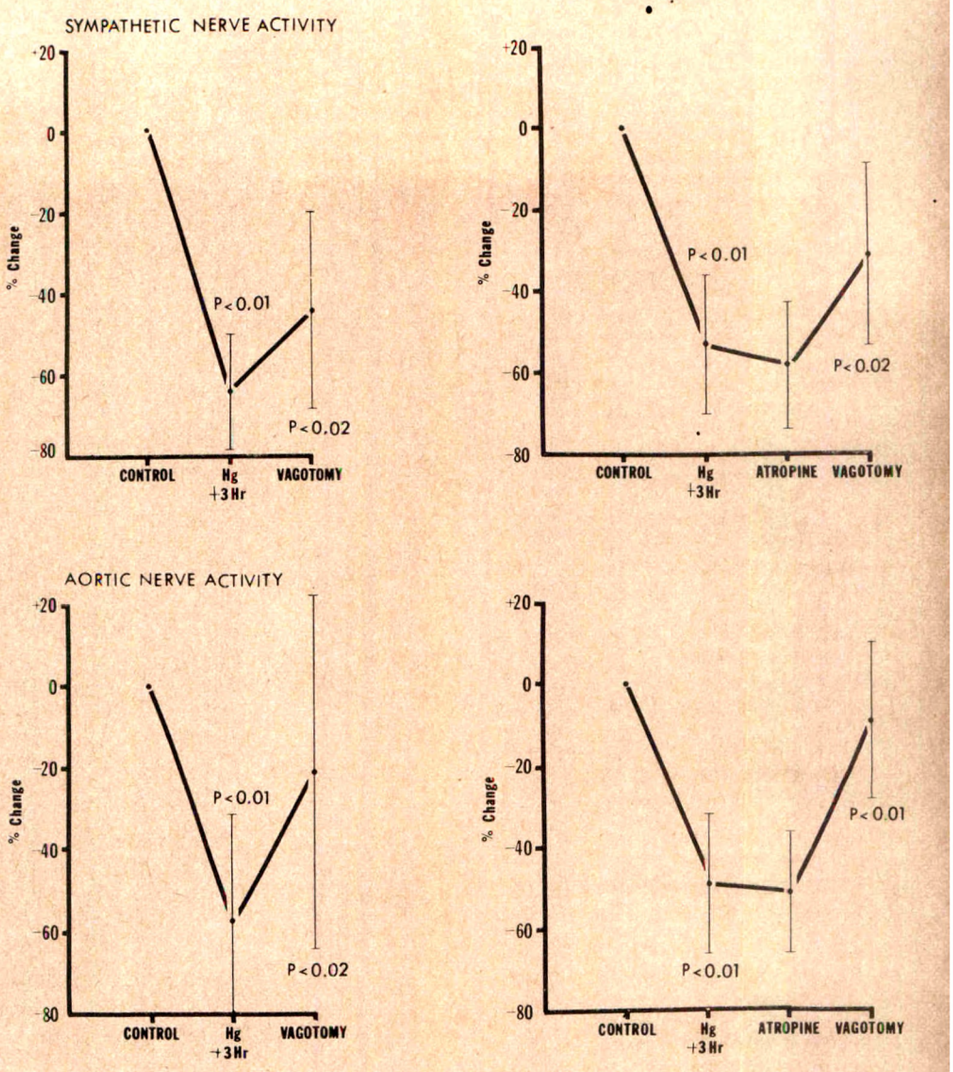

FIGURE 4. Average postganglionic sympathetic and aortic nerve activity changes before and during shock and after vagotomy in seven dogs (Group 1) **(left graphs)** and after atropine and subsequent vagotomy in five dogs (Group 2) **(right graphs)**. The changes are expressed in percent of control. **Horizontal bars** indicate standard deviations. Note the significant lowering of both nerve activity levels during shock and the rise after vagotomy with no increase after atropine.

shown that renal sympathetic activity increased less than activity to the intestine upon withdrawal of baroreceptor inhibition. In our two experiments in which both renal and splenic sympathetic nerve activities were recorded no difference in activity increase was seen after vagotomy. However, the activity only increased to about base-line level. Since the systemic baroreceptors (carotid sinus and aortic nerves) were left intact, no maximal sympathetic activity occurred because it was now inhibited to a certain degree by these baroreceptors. Elimination of systemic baroreceptors, superimposed on vagotomy, would probably have brought out the differences in the maximal sympathetic activity response of the two vascular beds. Nevertheless, a redistribution of sympathetic drive (and blood flow) after vagotomy in our shock experiments can be assumed from other studies.

Clinical implications: Since in man it is not possible to block vagal afferent activity selectively, the alternative is to increase pharmacologically the beta adrenergic sympathetic drive to the heart and the alpha adrenergic drive to the peripheral blood vessels.[20,33] We have found that this type of sympathetic augmentation in cardiogenic shock is most effective when drug combinations are used. Carefully titrated doses of isoproterenol producing beta adrenergic stimulation of the heart will result in increased cardiac output, and the addition of small doses of norepinephrine to supplement the inadequate peripheral sympathetic drive will produce elevation of mean systemic blood pressure to an optimal level. This may result in adequate coronary perfusion pressure, as we have shown in previous experiments.[20] Our approach appeared to compensate for the depressed sympathetic drive to the heart and the peripheral vascular system and to correct the effect of the positive feedback mechanism due to the vagal afferent reflex. Atropine did not lead to improved cardiac output or to increased renal sympathetic activity or, presumably, to advantageous redistribution of blood flow despite its effect of eliminating the relative bradycardia. These findings with atropine are in accord with those of Karsh et al.[34]

Accumulation of Gallium-67 in Regions of Acute Myocardial Infarction

The radionuclide gallium-67 has been shown to accumulate in a variety of inflammatory and neoplastic lesions, thereby permitting identification of these abnormalities by radioisotope imaging. We have found that ^{67}Ga also accumulates selectively in recently infarcted myocardium. Acute myocardial infarction was induced in dogs by ligation of the left anterior descending coronary artery, then ^{67}Ga (3 to 4 mc) was injected intravenously. Hearts were removed 24 hours later, and isotope localization was evaluated by an Anger camera and by autoradiography. In five of eight dogs, ^{67}Ga was found to accumulate preferentially in regions of visible infarction. Tissue creatine phosphokinase (CPK), measured in four of the five dogs, was greatly reduced and white blood cell infiltration was intense in the infarcted region. The infarcts of three dogs without preferential ^{67}Ga uptake showed lesser degrees of CPK reduction and white blood cell infiltration. Localization of ^{67}Ga in regions of acute myocardial infarction was also demonstrable by scanning intact, closed chest dogs. Hearts of two animals with transient (20 minutes) ischemia showed neither ^{67}Ga accumulation nor decreased CPK. Thus, ^{67}Ga localization discriminates infarcted from normal or only transiently ischemic myocardium. Unlike potassium and its analogs, ^{67}Ga scanning does not depend on resolution of "cold" areas nor is it likely to introduce ambiguities due to flow limitation of isotope delivery. For these reasons ^{67}Ga may prove particularly useful in the imaging of acute myocardial infarction in man.

It recently has become apparent that radioisotope techniques may offer important assistance in the detection of acute myocardial infarction.[1–13] Myocardial scanning agents currently in use (chiefly radioactive potassium and its analogs) depend on resolution of "cold" areas in which the lack of myocardial isotope uptake is interpreted as an infarcted region. A tracer with the ability to concentrate in infarcted tissue, thereby producing a "hot" area, would have the advantage of improved resolution and ease in interpretation. Moreover, an isotope specifically localizing in regions of acute myocardial infarction would be of particular use in discriminating zones that were merely receiving abnormal perfusion but had no actual tissue injury. This distinction cannot be made with any of the myocardial scanning agents now used.

The radionuclide gallium-67 has attained widespread use as a scanning agent having the capability of localizing in a variety of inflammatory lesions and neoplasms.[14–17] Because an inflammatory process is an intrinsic part of the evolution of acute myocardial infarction, we examined the ability of intravenously administered ^{67}Ga citrate to accumulate selectively in areas of recently infarcted canine myocardium.

Methods

Preparation of infarcts: Myocardial infarction was surgically induced in 15 dogs. After sodium pentobarbital anesthesia (30 mg/kg body weight, intravenously), the thorax was entered through a median sternotomy or a left lateral thoracotomy, the pericardium opened, and the left anterior descending coronary artery was ligated at the level of the lower margin of the left atrial appendage. Two control animals underwent 20 minutes of ischemia induced by temporary occlusion of the left anterior descending coronary artery. In one group of dogs (Group I) ^{67}Ga citrate (3 to 4 mc) was given intravenously immediately after operation, and the hearts were removed 24 hours after induction of myocardial infarction or control ischemia. The excised hearts were then studied with a scintillation camera and autoradiography; portions of infarcted and noninfarcted tissue were taken for histologic sections and tissue creatine phosphokinase (CPK) assay. A second series of animals (Group II) underwent surgical infarction, then were scanned in vivo 2, 3 and 4 weeks after infarction with 3 to 4 mc ^{67}Ga citrate given intravenously 24 to 48 hours before each scan.

Histologic and enzymatic studies: Myocardial infarction was documented by histologic sections of extirpated hearts and by tissue CPK assay. Histologic sections were stained with hematoxylin-eosin. Particular attention was

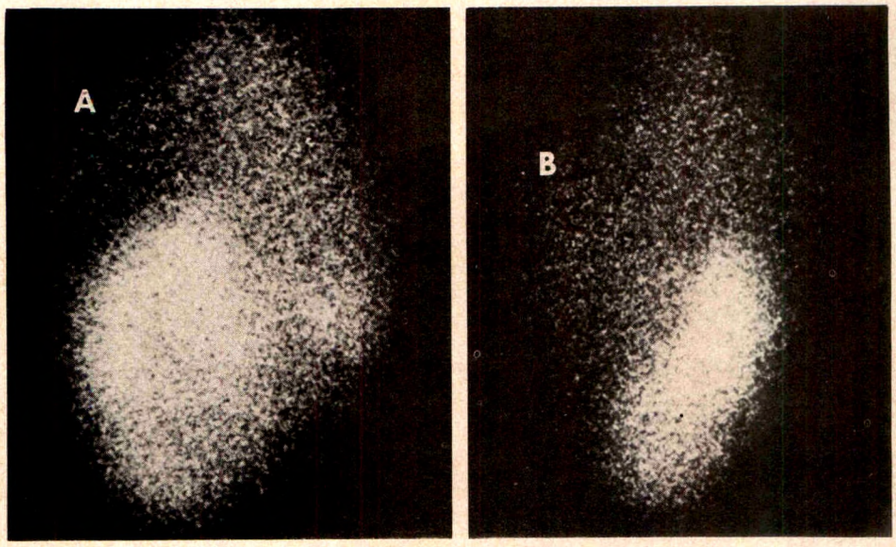

FIGURE 3. ^{67}Ga scintiphotographs of the whole excised heart 24 hours after infarction produced by ligation of the left anterior descending coronary artery. **A,** anterior view reveals a region of increased isotope accumulation extending along the interventricular groove **(sharply demarcated left margin)** nearly to the apex **(bottom). paid to degree of inflammatory cell infiltration in sections from both infarcted and noninfarcted regions. CPK assay was performed on full thickness punch biopsy specimens taken from both grossly normal and infarcted tissue. The tissue was prepared and assayed according to previously published techniques.[18] The range for normal tissue is 700 to 1,000 international units/mg wet weight.

Autoradiography: Autoradiography was performed by placing fresh or formalin-fixed 1 to 2 cm thick horizontal slices of the entire extirpated heart on Kodak medical X-ray film, then storing in total darkness at 0° C. The film was exposed to the tissue for 1 to 3 days and subsequently developed in a standard X-ray processing unit.

Scintigraphic technique: Isotope localization was determined in intact animals, extirpated whole hearts and transverse sections of whole hearts (perpendicular to the interventricular septum) with a Nuclear-Chicago Pho/Gamma High Performance scintillation camera using a large bore pinhole collimator. To form each image, 250,000 to 900,000 counts were collected for intact animals and 50 to 150,000 counts were accumulated for extirpated hearts and tissue slices. In all studies maximal sensitivity of gamma detection was set at 190 kev with a 35 percent window to encompass the 184 kev photopeak of ^{67}Ga.

All myocardial isotope scintigraphic data were analyzed with a Hewlett Packard Computer 5407A Scintigraphic Data Analyser. The raw data were stored in digital form on magnetic tape. Standard computer programs were used to subtract background counts and frame the raw data into images.

Extirpated hearts were imaged from both the anterior and lateral aspects. Intact animals were scanned in the left lateral position while sedated with diazepam and sodium pentobarbital. To further localize areas of isotope accumulation within the myocardium, a double isotope procedure was used in several animals. In these studies, the ^{67}Ga scintigraphic image was first stored on the 5407A computer system. Without moving the animal, a bolus of ^{99m}technetium-labeled albumin or ^{99m}technetium sulfur colloid was injected intravenously. The initial passage of the isotope through the heart was recorded and an image of the cardiac blood pool was made.

Results

Acute studies in extirpated hearts (Group I): Scintigrams and radioautographs of hearts extirpated 24 hours after coronary ligation and ^{67}Ga administration revealed localization of the isotope in the region of myocardial infarction. Studies of horizontal sections showed sharply delineated regions of ^{67}Ga uptake corresponding closely to portions manifesting grossly evident infarction (Fig. 1). Noninfarcted regions did not accumulate ^{67}Ga. The tendency of ^{67}Ga to accumulate selectively within infarcted tissue permits scintigraphic mapping of the extent of the infarction produced by coronary ligation (Fig. 2). The

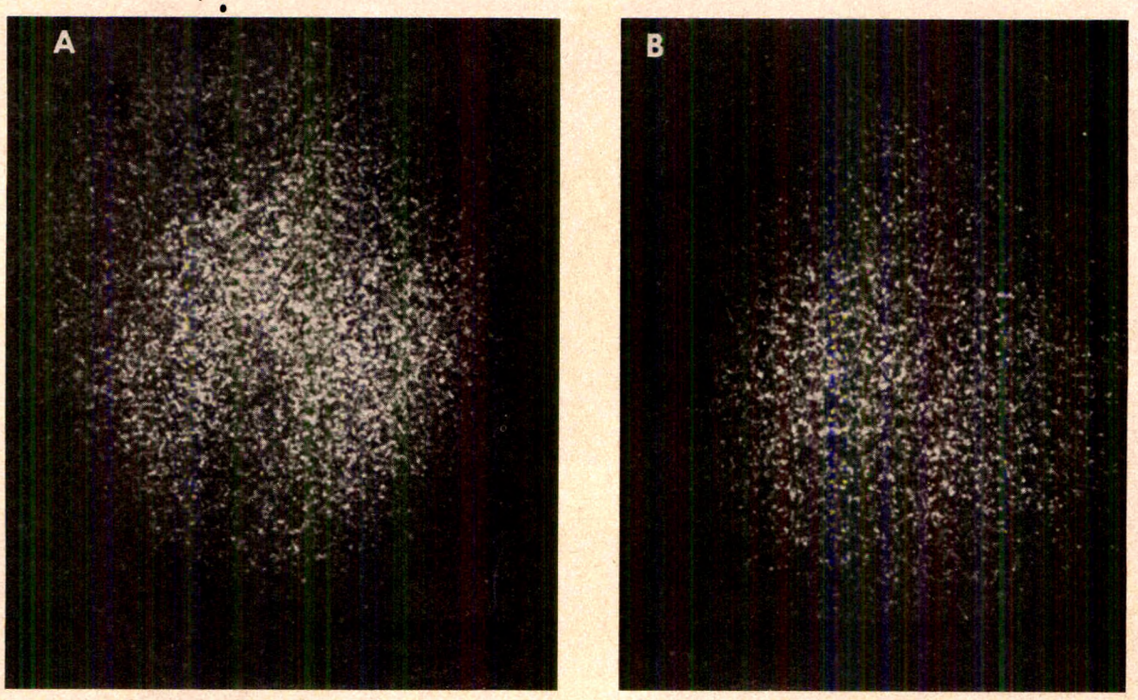

FIGURE 4. ^{67}Ga scintiphotographs of the whole excised heart 24 hours after ischemia induced by a 20 minute period of occlusion of the left anterior descending coronary artery. In contrast to Figure 3, no area of increased isotope uptake is observed. **A,** anterior view, orientation as in Figure 3A. **B,** left lateral view, orientation as in Figure 3B.

region of myocardial infarction was also delineated by anterior and lateral scintigrams of the whole extirpated heart (Fig. 3). In contrast, anterior and lateral scintigrams of extirpated hearts subjected to a 20 minute period of anterolateral ischemia 24 hours before study manifested no tendency for ^{67}Ga localization (Fig. 4). Lack of myocardial infarction in these two hearts in which ^{67}Ga was not selectively taken up was confirmed by enzymatic and histological studies (Table I).

Adequate scintigraphic evidence of ^{67}Ga localization was observed in five of eight extirpated hearts studied 24 hours after coronary ligation (Table I). Each of these hearts manifested histologic and enzymatic evidence of myocardial infarction. Scintigraphic evidence of ^{67}Ga localization was seen in those five hearts with the greatest severity of ischemic injury, as assessed by CPK reduction. Moreover, the three hearts with the most intense ^{67}Ga localization also demonstrated dense polymorphonuclear leukocyte infiltration of the infarcted region on histologic section. Conversely, this degree of ^{67}Ga accumulation was not seen in the absence of dense leukocyte infiltration.

Chronic studies in intact animals (Group II): When ^{67}Ga was injected 24 to 48 hours before study, adequate scintigraphic visualization of a region of ^{67}Ga uptake was obtained in the intact dog. As shown in Figure 5, radioisotope labeling of the cardiac blood pool demonstrated that this region of ^{67}Ga localization corresponds to the anterior and apical location of the surgically induced myocardial infarction. Accumulation of ^{67}Ga also was seen in areas of surgical scar. However, the region of myocardial infarction was readily distinguished from surgical scar by its proximity to the cardiac blood pool in multiple projections. Moreover, the scintigraphic appearance

Isotope localization is seen in the region of the heart **(center)** and liver **(bottom).** Isotope localization over the heart was not seen in sham-operated animals. **B,** left lateral scan of the cardiac blood pool was made after injecting ^{99m}Tc-albumin without moving either animal or gamma camera. Orientation as in **A. C,** an outline of the cardiac blood pool was made from the scan shown in **B** using a computer-linked "light pen." **D,** computer superimposition of the outline of the cardiac blood pool **(C)** on the ^{67}Ga scan **(A)** documenting anteroapical isotope uptake, corresponding to the site of infarction.

of ^{67}Ga localization in the region of myocardial infarction was similar whether the associated surgical scar resulted from left lateral thoracotomy or from midline thoracotomy.

Scans were obtained repeatedly after coronary ligation to evaluate the length of the postinfarction period during which ^{67}Ga localization was demonstrable. Because of the short half-life of ^{67}Ga (78 hours), no detectable isotope remained in the heart at the time of repeat administration of ^{67}Ga. As shown in Table II, all seven of the animals scanned at 2 or 3 weeks had positive scintigrams but none of the four animals studied at 4 weeks showed evidence of ^{67}Ga localization although each had had a positive scintigram 1 or 2 weeks previously. In each of these latter four dogs, absence of ^{67}Ga localization was confirmed

by scintigrams of the extirpated heart. Thus, in our animal model, myocardial infarction could be demonstrated by ^{67}Ga accumulation for a period of approximately 3 weeks after the ischemic insult.

In one control animal there was no evidence of ^{67}Ga localization in the vicinity of the heart. Isotope localization was observed in a second control animal, but this animal also had severe postoperative pericarditis.

Discussion

Our results indicate that ^{67}Ga accumulates selectively in freshly infarcted canine myocardium, thus permitting scintigraphic delineation of infarction in both extirpated hearts and in the hearts of intact animals. The intensity of ^{67}Ga uptake correlates with the severity of the ischemic damage and, in particular, with the density of polymorphonuclear leukocyte infiltration. This finding is consistent with the results of other investigators suggesting in vivo ^{67}Ga localization in activated neutrophils and histocytes[19–21] and suggests that ^{67}Ga enters or is retained within the infarcted region as a result of the inflammatory cell response to the ischemic tissue damage. This possibility is also supported by our finding that infarcted myocardium will accumulate ^{67}Ga for only about 3 weeks after the initiating ischemic insult, a time period comparable to the duration of the granulocyte and histocyte invasion of damaged myocardium.[22]

Advantages of method: Radioactive gallium may offer certain unique advantages in the scintigraphic localization and quantification of myocardial infarction. Because of its presumed relation to the biologic properties of ischemic damage, ^{67}Ga localization may be much more specific for regions of acute myocardial infarction than isotope techniques that primarily delineate the nature of coronary flow or the locus of tissues capable of active ion transport. Thus, in addition to recently infarcted tissue, the latter techniques will also yield "cold" areas corresponding to inadequately perfused myocardium (areas of ischemia but not necessarily infarction) and regions of old myocardial scar. Similarly, the presumed dependence of ^{67}Ga localization on cellular migration rather than coronary flow may allow more precise definition of the area of infarct. From a purely physical standpoint, a positive scan may offer greater resolution than a technique relying on the identification of "cold" regions. Since ^{67}Ga, which appears specific for areas of infarction, differs so completely from radioactive potassium and its analogs, which identify areas of poor perfusion, it is possible that maximal information may be obtained by combining these techniques.

Drawbacks of method: In addition to suggesting the potential utility of ^{67}Ga, our studies also indicate possible drawbacks in ^{67}Ga scanning for myocardial infarction. Only five of eight hearts with documented infarction had ^{67}Ga uptake. Thus, the apparent dependence of ^{67}Ga accumulation on an associated inflammatory cell response may render this technique relatively insensitive. Furthermore, the tendency of ^{67}Ga to accumulate in reticuloendothelial elements of liver and bone marrow[23] may introduce ambiguities into regions of the scan where these tissues are adjacent to the left ventricle. This is particularly likely in evaluating the diaphragmatic surface of the heart, which lies very near the region of the liver. The failure of mercury-labeled chlormerodrin in human trials[24] despite the promising results in experimental animals[2,25] also demonstrates that extrapolation from the experimental situation must always be made with caution.

Nevertheless, previous experience has shown that ^{67}Ga scanning is a safe and effective noninvasive method for evaluating patients with neoplastic and inflammatory disease. Our data suggest that ^{67}Ga photoscanning should be evaluated as a technique for the identification and localization of acute myocardial infarction in man.

Dimensional Changes of the Left Ventricle During Acute Pulmonary Arterial Hypertension in Dogs

EDWARD W. STOOL, MD*
CHARLES B. MULLINS, MD, FACC†
STEPHEN J. LESHIN, MD
JERE H. MITCHELL, MD, FACC

Dallas, Texas

Left ventricular dimensions and volumes were measured by an endocardial marker technique in eight closed chest dogs during progressive increases of 10 mm Hg in mean pulmonary arterial pressure. Right ventricular volumes were measured by biplane cineangiography.

Increasing mean pulmonary arterial pressure caused a progressive increase in right ventricular volume; at a mean pulmonary arterial pressure of 60 mm Hg, right ventricular end-diastolic volume increased by 48 percent and end-systolic volume by 50 percent. Left ventricular volumes began to decrease significantly at a mean pulmonary arterial pressure of 30 mm Hg, and when a mean pulmonary arterial pressure of 60 mm Hg was reached, left ventricular end-diastolic volume had decreased by 30 percent and left ventricular end-systolic volume by 19 percent. Changes in ventricular filling pressure directionally followed the volume changes of the respective ventricle. Left ventricular stroke volume decreased 45 percent at a mean pulmonary arterial pressure of 60 mm Hg but increasing heart rate prevented a decrease in cardiac output.

The decrease in left ventricular volume as pulmonary arterial pressure was increased was associated with a disproportionate reduction in the left ventricular septal-lateral axis. At end-diastole, this dimension decreased by 22 percent at a mean pulmonary arterial pressure of 60 mm Hg, the anterior-posterior axis decreased by 8 percent and the base-apex axis by 4 percent. A similar disproportionate decrease of the septal-lateral axis occurred at end-systole. Even at the modest increase in mean pulmonary arterial pressure to 20 mm Hg, only the septal-lateral dimension was significantly shortened, and the right ventricular end-diastolic volume had increased by 17 percent but left ventricular end-diastolic volume was not significantly changed. Thus, during acute pulmonary hypertension, the right ventricle progressively dilates resulting in a distinctive change in the shape of the left ventricle that suggests septal bulging and that may impair left ventricular function.

Alterations in the function of the left ventricle have been observed to occur with primary right ventricular overload states. Patients with cor pulmonale without evidence of other associated heart disease have been shown to have increased left ventricular end-diastolic and pulmonary capillary wedge pressures or depressed left ventricular function curves, or both.[1,2] Increased left ventricular filling pressure has been observed in experimental animals subjected to acute right ventricular overload states.[3,4]

That the mechanical effect of right ventricular distension on the cavity of the left ventricle may affect left ventricular function has been subsequently suggested by studies demonstrating alterations of passive ventricular pressure-volume relations by the degree of filling of the opposite ventricle.[5,6] Matching filling pressures during passive

distension of isolated hearts with those obtained in in vivo volume-loaded hearts, Taylor et al.[6] showed that the distensibility of either ventricle was decreased proportionately to the filling of the opposite chamber and suggested that this phenomenon was secondary to both ventricles sharing a common septum and fiber bundles.

The purpose of this study was to investigate any alteration in left ventricular dimensions that might accompany left and right ventricular volume changes in the intact animal subjected to acute pulmonary hypertension.

Materials and Methods

Eight mongrel dogs weighing between 17 and 25 kg were anesthetized with pentobarbital sodium (15 mg/kg body weight intravenously) and placed on a Harvard respirator pump. A left lateral thoracotomy was performed, and six lead beads were positioned near the left ventricular endocardium to delineate the major and two minor axes of an assumed ellipsoidal shell of muscle adjacent to the left ventricular cavity according to the method of Mitchell and coworkers.[7-9] The distance between the base and apex beads defines the base-apex axis (L_1), that between the anterior and posterior beads is the anterior-posterior axis (L_2) and that between the septal and lateral beads is the septal-lateral axis (L_3). After bead placement the pericardium was loosely reapposed and the thoracotomy closed.

The movements in space between the three pairs of beads were calculated from biplane cinefluorographic exposures taken on 35 mm film at intervals of 1/60 second. Measurements of the spatial lengths of the three axes in the anteroposterior and lateral projections were made from the 35 mm film on a specially modified digitizing system. A cinefluorographic film of a 30 mm steel ball was photographed at the same position as the left ventricle and used to correct for magnification and distortion. Left ventricular volume was calculated by inserting the three ventricular dimensions (L_1, L_2 and L_3) into the formula for the volume of a nonprolate ellipsoid:

$$\text{Volume} = \tfrac{4}{3}\pi abc$$

where $a = L_1/2$, $b = L_2/2$ and $c = L_3/2$.

All calculations were performed on a digital minicomputer using paper tape input and teletype output. All volume and dimensional data represent the mean values of measurements of three representative beats at each value for mean pulmonary arterial pressure.

After a minimum of 3 weeks after bead placement each dog was preanesthetized with morphine sulfate (3 mg/kg body weight subcutaneously), anesthetized with pentobarbital sodium 30 minutes later (15 mg/kg intravenously), intubated and placed on a Harvard respirator. Fluid-filled catheters were positioned by way of peripheral vessels into the left ventricle (National Institutes of Health, no. 8F), right ventricle (Gensini, no. 8F) and ascending aorta (Cournand, no. 8F); a triple lumen balloon catheter (Dotter-Lukas, no. 8F) was positioned in the main pulmonary artery. All pressures were measured with Statham P23Db transducers and recorded with the electrocardiogram and cinefluorographic frame marker on a multichannel photographic recorder (Electronics for Medicine DR-8) at a paper speed of 100 mm/sec. Cardiac output determinations were made by injecting indocyanine green dye into the pulmonary artery and sampling from the aorta using a Harvard withdrawal pump and a Beckman densitometer.

With the balloon catheter deflated, control biplane cinefluorographic films of the left ventricle and simultaneous pressures were recorded immediately after determination of cardiac output by indicator-dilution technique. This sequence was then repeated as the pulmonary arterial balloon was progressively inflated so as to achieve 10 mm Hg increments in mean pulmonary arterial pressure from 20 to 60 mm Hg. After each increment in mean pulmonary arterial pressure approximately 10 minutes was allowed for stabilization of hemodynamic variables. Arterial blood gas levels were determined immediately before each study and monitored frequently throughout the study. The rate and depth of respiration were changed and supplemental oxygen utilized as necessary to maintain appropriate arterial pH, PCO_2 and PO_2 values.

After completion of the left ventricular dimension studies, the pulmonary arterial balloon was deflated for approximately 30 minutes. It was then inflated sequentially exactly as before, but biplane cineangiograms of the right ventricle in the posteroanterior and lateral views were taken at a rate of 60 frames/sec immediately after pressure measurements at each level of mean pulmonary arterial pressure. The angiography was performed under a pressure of 200 lb/sq. in. utilizing a Cordis injector and with 1 ml/kg of Renografin 76® contrast medium. Recordings were made simultaneously of pressures, electrocardiogram and cinefluorographic frame markers. The end-systolic and end-diastolic cinefluorographic frames were traced and used to calculate right ventricular volumes by the longest measured length method of Dodge, which has proved to be an accurate method of measurement of right ventricular volume.[10,11]

Results

Hemodynamics: Table I shows the mean hemodynamic data for the eight dogs, and Figure 1 shows the influence of increasing mean pulmonary arterial pressure on heart rate, aortic pressure and right ventricular and left ventricular pressures. Each point on the individual graphs represents the mean value for eight dogs and the brackets indicate ±1 standard error of the mean. Heart rate began to increase significantly at a mean pulmonary arterial pressure of 40 mm Hg ($P < 0.01$) reaching a maximum at 60 mm Hg. Mean aortic pressure increased slightly from control level at a pulmonary arterial pressure of 50 mm Hg ($P < 0.025$) and decreased at a mean pulmonary arterial pressure of 60 mm Hg to a value not significantly different from control level. The aortic diastolic pressure increased progressively with increasing pulmonary hypertension to a peak at a mean pulmonary arterial pressure of 50 mm Hg ($P < 0.02$) and decreased slightly toward the control value at a mean pulmonary arterial pressure of 60 mm Hg. Systemic vascular resistance, not illustrated, increased very slightly with increasing mean pulmonary arterial pressure from a control value of 3,510 dynes sec cm^{-5} to 4,230 dynes sec cm^{-5} at a mean pulmonary arterial pressure of 60 mm Hg; this change was not statistically significant.

Right ventricular peak systolic and end-diastolic pressures increased progressively as mean pulmonary arterial pressure increased. Left ventricular peak systolic pressure rose slightly from control level at a

C = control; CO = cardiac output (liters/min); EF = ejection fraction (stroke volume/end-diastolic volume); HR = heart rate (beats/min); LVEDP = left ventricular end-diastolic pressure (mm Hg); LVEDV = left ventricular end-diastolic volume (cc); LVESV = left ventricular end-systolic volume (cc); LVP = left ventricular pressure (mm Hg); MAP = mean arterial pressure (mm Hg); NS = not significant; *P* = probability; PA = pulmonary arterial pressure (mm Hg); RVEDP = right ventricular end-diastolic pressure (mm Hg); RVP = right ventricular pressure (mm Hg); SE = standard error of the mean; SV = stroke volume (cc); SVR = systemic vascular resistance (dynes sec cm^{-5}).

mean pulmonary arterial pressure of 30 mm Hg (P <0.02) and then fell to a level not significantly different from the control value at mean pulmonary arterial pressures of 50 and 60 mm Hg. Left ventricular end-diastolic pressure began to decrease significantly at a mean pulmonary arterial pressure of 40 mm Hg.

Left ventricular volumes: Table I shows the mean data for the changes in left ventricular volume for the eight dogs, and Figure 2 shows the effect of acute increments in mean pulmonary arterial pressure on mean left ventricular volume. Left ventricular end-diastolic volume began to decrease significantly at a mean pulmonary arterial pressure of 30 mm Hg and was reduced by 30 percent at a mean pulmonary arterial pressure of 60 mm Hg (P <0.001). Left ventricular end-systolic volume decreased progressively to 19 percent at a mean pulmonary arterial pressure of 60 mm Hg (P <0.001). Left ventricular stroke volume decreased to 45 percent at a mean pulmonary arterial pressure of 60 mm Hg (P <0.001). Cardiac output did not change significantly in response to progressive pulmonary hypertension, being maintained by increasing heart rate until cardiovascular collapse occurred at mean pulmonary arterial pressures greater than 60 mm Hg. Left ventricular ejection fraction remained unchanged until a mean pulmonary arterial pressure of 50 mm Hg was reached and then began to decrease.

Left ventricular axis lengths: Table II shows the mean data for the changes in individual axis lengths for the eight dogs, and Figure 3 shows the effect of increasing mean pulmonary arterial pressure on the L_1, L_2 and L_3 axis lengths at end-diastole and end-systole, as well as the degree of shortening (axis length at end-diastole minus the axis length at end-systole). At end-diastole the septal-lateral axis (L_3) decreased 23 percent from the control value at a mean pulmonary arterial pressure of 60 mm Hg (P <0.001), whereas the anterior-posterior (L_2) and base-apex (L_1) axes decreased 8 and 4 percent, respectively. At each level of mean pulmonary arterial pressure above the control level, the L_3 axis at end-diastole was significantly smaller than the L_2 or L_1 axis (P <0.001).

At end-systole (Fig. 3), the L_3 axis decreased 15 percent from the control value at a mean pulmonary arterial pressure of 60 mm Hg (P <0.001); the L_2 and L_1 axis lengths at end-systole did not significantly change in response to increasing mean pulmonary arterial pressure. The total axis excursion or degree of systolic shortening of the L_3 axis decreased 53 percent from the control value at a mean pulmonary arterial pressure of 60 mm Hg; the L_2 and L_1 axes were reduced by 20 and 25 percent, respectively.

Right ventricular volumes: Table III shows the mean data for changes in right ventricular volumes. Right ventricular end-diastolic and end-systolic vol-

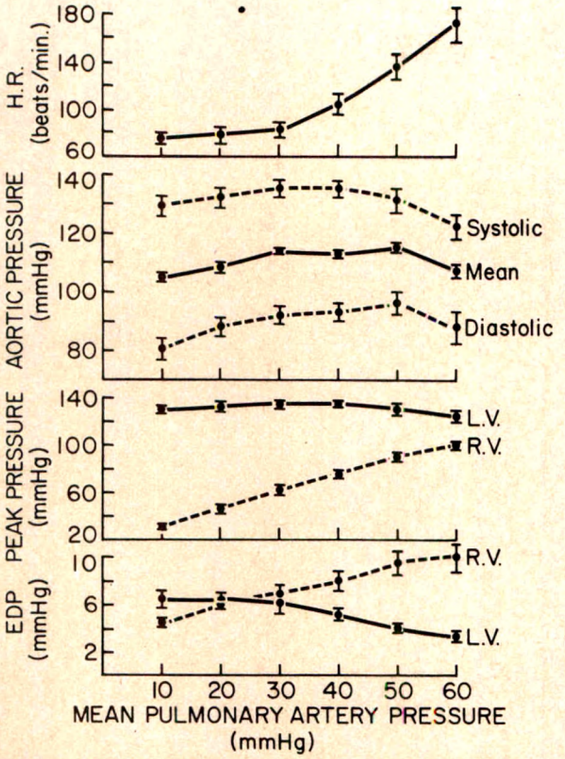

FIGURE 1. Effect of progressive pulmonary hypertension on hemodynamics. Each point represents the mean value for eight dogs and brackets represent the standard error of the mean. EDP = end-diastolic pressure; H.R. = heart rate; L.V. = left ventricle; R.V. = right ventricle.

umes increased approximately 50 percent from control values at a mean pulmonary arterial pressure of 60 mm Hg. Total stroke volume increased from 22 ml during the control period to 32 ml at a mean pulmonary arterial pressure of 60 mm Hg. Data on forward stroke volume were not obtained in this study, but in previous work marked tricuspid regurgitation was noted.[12] Right ventricular ejection fraction remained essentially unchanged.

Discussion

Hemodynamic Effects of Acute Pulmonary Hypertension

In this study the maximal mean pulmonary arterial pressure tolerated by anesthetized dogs subjected to acute balloon-induced pulmonary hypertension was 60 mm Hg. Exceeding this level or holding it for any prolonged period of time resulted in rapid deterioration, which appeared to be related to an inability to further increase heart rate in response to decreasing left ventricular stroke volume. This deterioration was signaled by a sudden reduction in heart rate or mean aortic pressure, or both. This sudden deterioration was usually reversible when the balloon was immediately deflated; when deflation was delayed, the animals were often unable to tolerate lesser degrees of pulmonary hypertension during subsequent attempts to increase pulmonary arterial pressure sequentially.

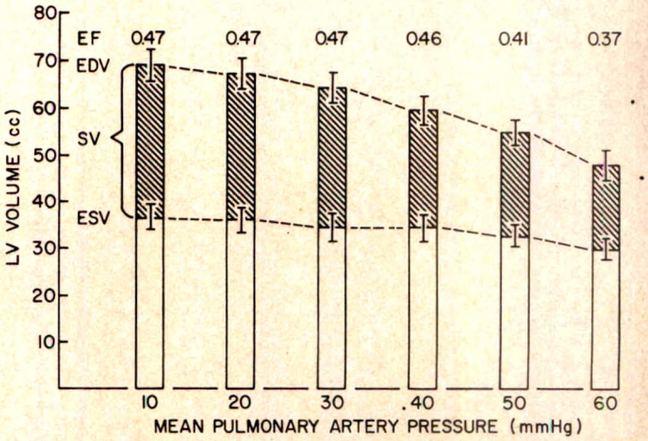

FIGURE 2. Effect of progressive pulmonary hypertension on left ventricular volumes. Volumes represent mean data from eight dogs and brackets represent the standard error of the mean. EDV = end-diastolic volume; EF = ejection fraction; ESV = end-systolic volume; LV = left ventricular; SV = stroke volume.

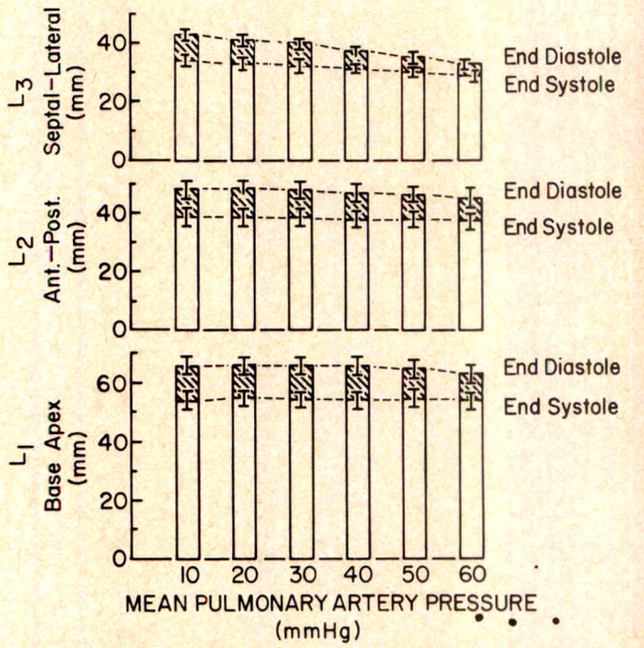

FIGURE 3. Effect of progressive pulmonary hypertension on individual left ventricular axis lengths at end-diastole and end-systole. The **shaded** area of each bar represents the shortening of each axis during systole. L_1 = base-apex length; L_2 = anterior-posterior length; L_3 = septal-lateral length.

This finding may reflect the combined effects of time and stress on our closed chest animals or may represent some as yet undefined structural alteration secondary to acute severe and sustained right ventricular pressure overload.

Laks et al.[13] subjected conscious dogs to acute increases in balloon-induced pulmonary hypertension and classified their hemodynamic response into an "initial" phase in which cardiac output increased and a "terminal" phase in which it decreased. The observed sudden hemodynamic deterioration in our an-

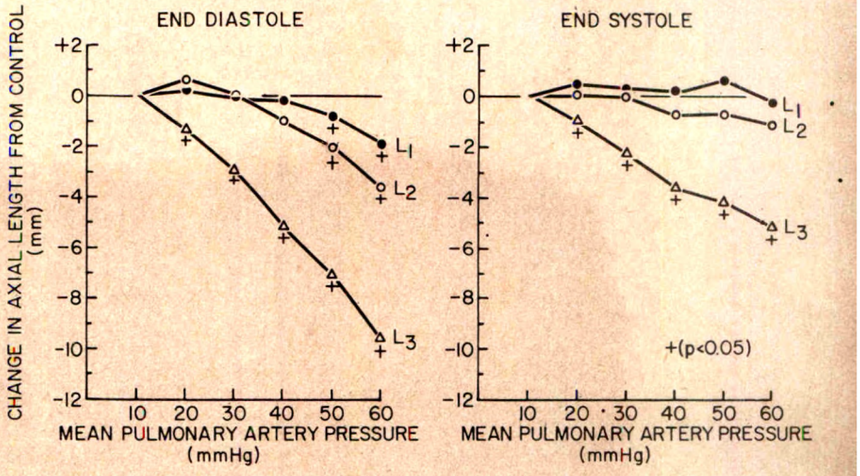

FIGURE 4. Effect of progressive pulmonary hypertension on the change in axis length from control. Positive values along the ordinate represent increase in axis length; negative values represent decrease in axis length. Each individual point represents the mean value for eight dogs, and crosses represent statistical significance to at least $P < 0.05$ (paired Student t test with respect to control value). L_1 = base-apex length; L_2 = anterior-posterior length; L_3 = septal-lateral length.

imals at a mean pulmonary arterial pressure of 60 mm Hg or more must roughly correspond to this "terminal" phase. Differences in heart rate, cardiac output and systemic vascular resistance between the two studies are probably explained by the effects of anesthetic agents or the unconscious state, or both, on autonomic tone or reflexes. The mean peak right ventricular systolic pressure of 100 mm Hg obtained in our study agrees closely with that of 95 mm Hg obtained in the study by Laks et al.,[13] and the peak right ventricular end-diastolic pressure obtained in both studies was 10 mm Hg. This finding suggests that these are the approximate maximal pressures obtainable by the dog right ventricle in response to acute pressure overload.

Ventricular Volumes

Right ventricular angiography was deferred until completion of the left ventricular dimension studies to avoid any depressant effect of contrast medium on left ventricular function.[14] The dogs were thereby subjected to prolonged experimental time, sequential reinflation of the pulmonary arterial balloon, and the possibly depressing effect of angiography itself—factors undoubtedly contributing to the inability of some of our animals to tolerate high levels of pulmonary hypertension in this latter part of the study. However, the observed increases in right ventricular end-diastolic and end-systolic volumes in response to progressive pulmonary hypertension (Table III) were qualitatively identical to those observed in a previous study from our laboratory[12] in which right ventricular biplane cineangiograms were obtained in closed chest anesthetized dogs at similar increments of balloon-induced pulmonary hypertension. In that study as in the present one, both right ventricular end-diastolic and end-systolic volumes increased approximately 50 percent from control level at a mean pulmonary arterial pressure of 60 mm Hg.

Left ventricular end-diastolic and end-systolic volumes began to decrease significantly at a mean pulmonary arterial pressure of 30 mm Hg. Neither was significantly altered at a mean pulmonary arterial pressure of 20 mm Hg. However, there was a significant (17 percent) increase in right ventricular end-diastolic volume at this mild degree of pulmonary hypertension. Left ventricular volumes markedly decreased at mean pulmonary arterial pressures of 40 to 60 mm Hg. These levels of pulmonary hypertension have previously been shown[12] to be associated with marked increases in right ventricular volume (50 percent) and with the onset of progressive tricuspid regurgitation. With the onset of tricuspid regurgitation, forward stroke volume of the right ventricle decreased.

Left Ventricular Dimensions

Analysis of the effect of acute pulmonary hypertension on left ventricular dimensions demonstrated that a characteristic distortion of left ventricular geometry accompanies the increase in right ventricular volumes. Specifically, a disproportionate shortening of the septal-lateral axis occurs at both end-diastole and end-systole at all levels of pulmonary hypertension. This is further illustrated in Figure 4, in which the mean axis data are plotted as the change in individual axis length from control values, and the statistical significance is denoted by a cross. It is obvious from this figure that at a mean pulmonary arterial pressure of 20 mm Hg the L_3 axis is significantly shortened during both end-diastole and end-systole, whereas the L_1 and L_2 axes are either unchanged or slightly (but not significantly) lengthened with respect to the control value. This selective distortion of left ventricular geometry was observed to accompany an increase in right ventricular volumes at a mild degree of pulmonary hypertension and before any significant decrease in left ventricular end-diastolic volume occurred.

In our study reductions in left ventricular end-diastolic volume were associated with an increase in heart rate. It has been shown[15,16] that increasing

heart rate characteristically causes a reduction in left ventricular end-diastolic volume. It is therefore likely that some of the observed decrease in end-diastolic volume during the progressive pulmonary hypertension was due to the associated tachycardia. The observed changes in left ventricular shape cannot be attributed to the tachycardia since studies[17] in conscious, chronically instrumented dogs indicate that tachycardia causes the left ventricle to decrease its size symmetrically.

In a recent report, Urschel et al.[18] utilized endocardial markers in an isolated dog heart preparation and observed alterations in left ventricular dimensions after volume loading to high right ventricular filling pressures while holding left ventricular stroke volume constant. The 22 percent decrease in the septal-lateral dimension during end-diastole which we observed at a mean pulmonary arterial pressure of 60 mm Hg exceeds but is directionally consistent with the 13.3 percent decrease in the septal-free wall dimension at end-diastole reported in the latter study when right ventricular end-diastolic pressure was elevated 10 mm Hg above the control level. Urschel et al.[18] found a 7 percent increase in the end-diastolic anterior-posterior dimension in a similar investigation, whereas we observed a 4 percent decrease in this dimension. This difference probably reflects the fact that a constant left ventricular stroke volume was maintained in their study by volume infusion of the left ventricle, whereas progressive right ventricular outflow obstruction led to a progressive decrease in left ventricular volume in our intact animals.

In a previous study from our laboratory, Mitchell and Mullins[7] determined the degree of systolic shortening of the L_1, L_2 and L_3 axes in more than 40 dogs previously subjected to endocardial bead placement as in this study. They found that the L_1 (base-apex) axis shortened 4 percent with each cardiac cycle, whereas the L_2 (anterior-posterior) and L_3 (septal-lateral) axes each shortened 10 percent. In our study there was a 53 percent reduction from the control value in the degree of systolic shortening of the L_3 axis at a mean pulmonary arterial pressure of 60 mm Hg compared with reductions of 25 and 20 percent for the L_2 and L_3 axes, respectively. Therefore, during each cardiac cycle at high levels of pulmonary arterial pressure there is a marked decrease in the degree of shortening of the septal-lateral axis which is out of proportion to the decrease in shortening observed in the other two axes.

Role of Septal Bulging

It is attractive to attribute this selective constriction of the left ventricular septal-lateral axis in the setting of acute pulmonary hypertension and increased right ventricular volumes to a bulging of the interventricular septum toward the cavity of the left ventricle. On right ventricular angiograms in the lateral view, the interventricular septum appears increasingly flat and less convex at increasing pulmonary arterial pressures, and this appearance also suggests encroachment on the cavity of the left ventricle.

In describing patients with isolated atrial septal defect and evidence of left ventricular decompensation, Dexter[19] suggested that bulging of the interventricular septum into the left ventricular cavity secondary to a markedly distended right ventricle may play an etiologic role. He coined the term "reversed Bernheim effect," likening this phenomenon to that described by Bernheim, in which right ventricular outflow was obstructed by septal hypertrophy and contributed to inordinate right ventricular failure in patients with pure left ventricular obstructive lesions.[20] Another explanation of our findings is that distortion of the septal fibers of the left ventricle caused by dilatation of the right ventricle might cause the change in the septal-lateral axis.

Our investigation clearly shows a selective change in left ventricular geometry resulting from right ventricular pressure overload in the closed chest dog. The distortion in geometry of the left ventricle shown by dimensional studies may contribute significantly to the apparent decrease in left ventricular compliance observed in volume-loaded animal preparations subjected to right ventricular pressure overload. Perhaps the clinical counterpart of this finding is seen in unexplained increases in left ventricular filling pressure observed in conjunction with primary right ventricular overload states in man.

Ventricular Conduction Delay and Asystole During Systemic Hyperkalemia

PHILIP O. ETTINGER, MD, FACC
TIMOTHY J. REGAN, MD
HENRY A. OLDEWURTEL
MOHAMMAD I. KHAN, MD

Newark, New Jersey

Systemic hyperkalemia was induced in 30 intact dogs to evaluate electrophysiologic and hemodynamic alterations caused by excess of potassium (K^+) ion. Sequential changes included atrioventricular junctional delay and block, followed by acceleration of junctional pacemakers and conduction delays in the ventricular specialized tissue and ventricular muscle. These resulted in unusual arrhythmias difficult to interpret in the peripheral electrocardiogram. As the level of potassium progressively rose, terminal Purkinje or Purkinje-muscle block was the dominant mechanism of arrest, with conduction through the ventricular specialized conduction system continuing at a regular rate even after asystole. The duration and amplitude of the intramural complexes were consistently reduced throughout the heart wall, whereas intramural conduction was progressively prolonged with late and inconstant changes in activation sequence. Ventricular pacing thresholds increased progressively, but were attainable even after asystole in some cases. The enhanced plasma K^+ was associated with accumulation of K^+ and sodium (Na^+) in myocardial tissue. A relatively uniform distribution of these ions from endocardium to epicardium is postulated to be a requirement for progressive conduction delay, lack of ectopic beats and asystole. Systemic arterial pressure and coronary blood flow were maintained until very high levels of K^+ were reached. Although left ventricular end-diastolic pressure increased progressively, the maximal rate of rise of left ventricular pressure (dP/dt max) was reduced only at a K^+ level of 11 mEq/liter. Myocardial ischemia was not present, thus suggesting that the abnormal ventricular function may have been secondary to conduction delays.

Increased extracellular potassium ion (K^+) and hypoxia similarly alter the action potential of isolated cardiac muscle.[1–3] However, the nodal, Purkinje and heart muscle cells have different sensitivities to acutely increased extracellular K^+.[3] This study was designed to determine the relation of conduction delay in the fascicular system of the left ventricle to intramural conduction during a period of gradual plasma potassium increments. Determination of the relative degree of depressed impulse conduction in the different segments of the conduction system not only may clarify the mechanism of asystole but also may, by contrast, facilitate understanding of the conditions underlying arrhythmogenesis during local intracoronary K^+ infusion.[4] In addition, the relative uniformity of altered myocardial cation composition has been assessed, as well as myocardial function and the response of the coronary circulation during hyperkalemia.

Methods

Healthy male mongrel dogs of similar ages, weighing 19 to 35 kg, were studied. In all animals, premedication was effected with morphine sulfate, 3 mg/kg, and anesthesia was induced with 12 mg/kg of intravenously adminis-

tered sodium pentobarbital. After endotracheal intubation and placement of the animal in a left lateral position, respirations were maintained with a mechanical respirator. Surgical incisions exposed jugular, carotid, axillary and femoral vessels for catheterization. Several aspects of hyperkalemia were evaluated, including specialized fiber activation, transmural electrographic changes, alterations of ventricular function and coronary blood flow and changes in ventricular pacing threshold and myocardial ion distributions. Each animal was included in at least one phase of these investigations.

To monitor hemodynamics, a saline-filled no. 8F Goodale-Lubin catheter was placed, under fluoroscopic control, in the left ventricle from the axilla and connected to a Statham P23Gb pressure gauge, the electrical output of which was displayed and recorded on an Electronics for Medicine DR-8 photographic recorder. The first derivative of left ventricular pressure rise (dP/dt) was obtained by resistance-capacitance differentiation of the pressure pulse. Another no. 8F Goodale-Lubin catheter was advanced by way of a jugular vein into the mid to high coronary sinus and connected to tubing used for infusion of saline solution. A femoral vein was used for infusion.

For specialized fiber recording, an electrode catheter of the tri-polar Castillo type (Electro-Catheter Corp., Rahway, N. J.) was thermally preshaped in hot water by curving the distal 7 cm into a "J," then passed through a carotid artery into the region of the right coronary cusp of the aortic valve. From this location it is possible to record a His bundle electrogram.[5–7] Recordings with the distal (close bipolar) pair were made utilizing a multiple electrode switch box (Electronics for Medicine), the output of which was led into the alternating current input of an electrocardiographic preamplifier and recorded on photographic paper at a speed of 200 mm/sec. A second similar electrode catheter was advanced through the other carotid artery into the left ventricle and directed anteriorly to record from a branch of the peripheral Purkinje radiation of the left bundle branch (or anterior false tendon). Impulses were filtered at 40 to 500 cycles/sec. Recording from the bundle branch has been similarly demonstrated by this technique in the dog[5,6] and in man.[7,8] The bipolar electrogram from this site was recorded simultaneously with the His bundle electrogram and a peripheral electrocardiographic lead, usually lead II. To ensure that a portion of the QRS complex was not isoelectric in that lead, the other two standard leads were also recorded with the electrograms. Early in the study, several animals underwent pacing from the right atrium at rates 5 to 10 beats/min in excess of sinus rate to maintain rate constancy, but this procedure was abandoned because of the early development of block at the atrioventricular (A–V) junction.

H–Q (or H–V, the interval from the first rapid deflection of the His bundle complex to the onset of the QRS complex), H–a (the interval from the His bundle to the false tendon complex) and QRS duration were all measured by hand in three representative beats at each measurement period and the means recorded to the nearest 0.2 msec.

Coronary blood flow was determined at rest and during induced hyperkalemia by retrograde injection of a solution of krypton-85 into the coronary sinus and observing the subsequent washout with a precordial scintillation counter.[9] Coronary blood flow (CBF) was calculated by the relation $CBF = (0.693 \times 100)/t_{1/2}$, where $t_{1/2}$ is the time in minutes required for decline of radioactivity to half of its value.

For implantation of transmural electrodes, a left thoracotomy and pericardiotomy were performed after anesthesia, and the heart was suspended in a pericardial cradle. Bipolar electrodes[10,11] made of Teflon®-coated stainless steel wire formed into small hooks (diameter 0.007 inch, Medwire Corp., Mt. Vernon, N. Y.) were placed through hypodermic needles into the endocardium and epicardium of

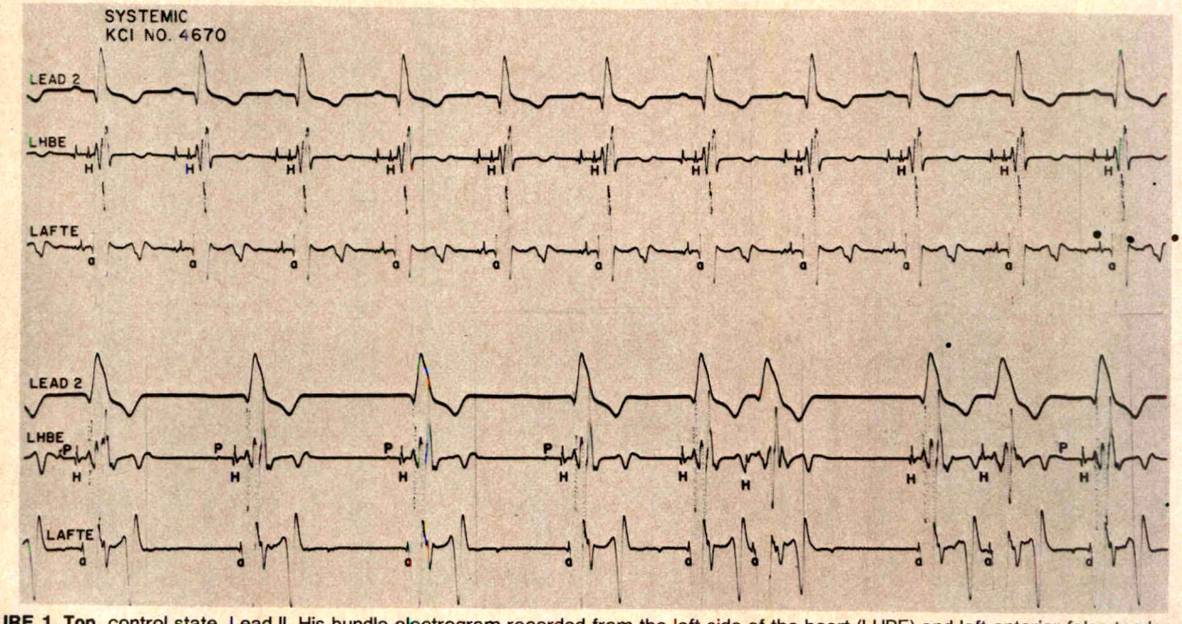

FIGURE 1. Top, control state. Lead II, His bundle electrogram recorded from the left side of the heart (LHBE) and left anterior false tendon electrogram (LAFTE). His (H) and bundle branch (a) impulses precede each QRS. **Bottom,** during hyperkalemia. The QRS complex is wider and slurred, although its configuration has not changed. P waves are absent from the peripheral electrocardiogram but are seen in LHBE to precede the first four beats. The fifth beat probably is of junctional origin (no P wave); all beats, however, are preceded by H and a impulses although these are slurred with the H–Q and H–a intervals prolonged. In this and all succeeding electrograms, paper speed = 200 mm/sec, time lines 1/sec except as otherwise noted.

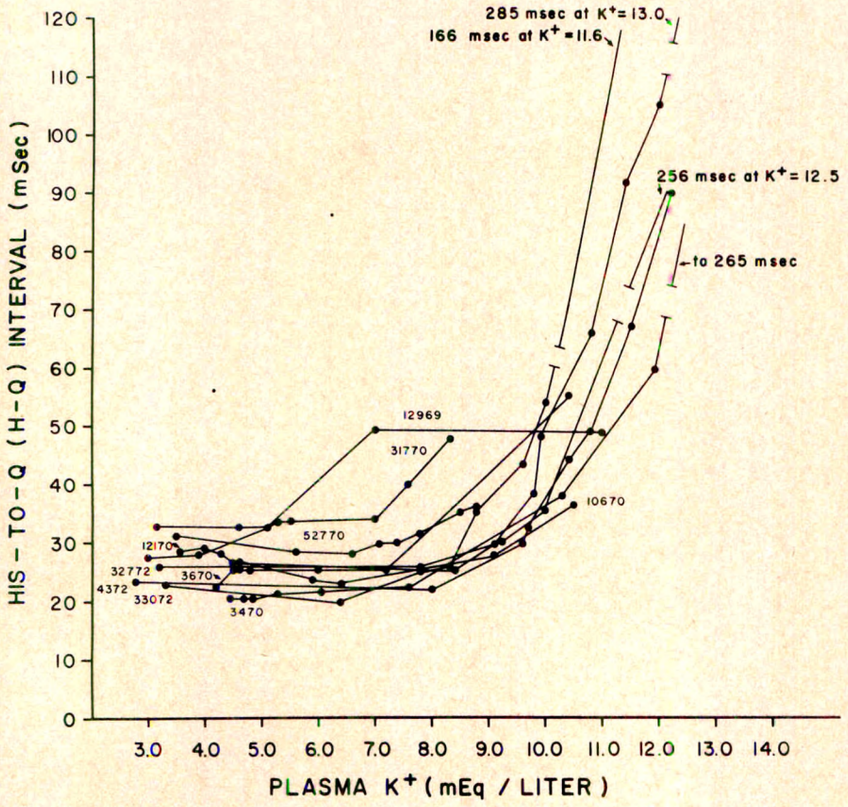

FIGURE 2. His–Q interval as a function of increasing plasma K^+. Major increases in the His–Q interval occur after a K^+ level of 9 to 10 mEq/liter. Several animals showed a transient shortening of the His–Q interval as K^+ increased in the range of 5 to 8 mEq/liter. (Numbers identify individual animals.)

Epicardial	100	69 ± 5‡	42 ± 10‡
Electrogram Q–T_c (msec)			
Endocardial	313 ± 11	300 ± 10§	263 ± 21§
Epicardial	308 ± 11	279 ± 11‡	256 ± 25§
Transmural (endocardial-epicardial) conduction time (msec)	17 ± 0	21 ± 2§	42 ± 8§

* Moderate hyperkalemia was at $K^+ \sim 8$ to 10.5 mEq/liter; severe hyperkalemia was the last recording before asystole, at $K^+ \sim 11$ to 15 mEq/liter.

† $P < 0.01$ compared with control; ‡ $P < 0.001$ compared with control; § $P < 0.005$ compared with control.

Since K^+ is known to reduce action potential height and duration and to prolong conduction and was assumed to alter local electrograms similarly, a one-tailed t test was used in these statistical calculations. Changes in voltage, Q–T_c interval and conduction time occurred in the same direction in all animals.

the left ventricular free wall midway between the apex and the base. These electrode pairs were 1 to 2 mm apart after placement, with individual diameters of 0.005 inch. The endocardial and epicardial electrodes were placed radially in relation to each other, that is, along an imaginary line traversing the free wall perpendicularly. These bipolar wire pairs were led through the multiple electrode switch box; intramural electrograms were filtered at 0.1 to 2,000 cycles/sec and recorded at 200 mm/sec; the first derivative of rise in voltage (dV/dt) of each was also obtained by resistance-capacitance differentiation. After satisfactory electrode placement, as evidenced by recording of a single sharp deflection sometimes followed by S–T segment displacement, the chest was closed and the animal allowed to rest until the S–T injury disappeared from the electrograms, a period of approximately 1 hour.

After recording of the endocardial and epicardial electrograms, the absolute height of the electrographic spike was measured at each stage of infusion and expressed as percent of control. The individual Q–T_c duration at both myocardial levels was calculated as Q–T_c = observed Q–T/$\sqrt{\text{R–R}}$ interval. The time between the peaks of the endocardial and epicardial complexes was measured as the transmural conduction time. DV/dt max was recorded intermittently and expressed as a percent of the control level of dV/dt max.

Bipolar epicardial and endocardial pacing thresholds were subsequently determined at rest and during hyperkalemia through these intramural electrodes with a Medtronic model 5737 pacemaker, calibrated to deliver impulses of known strength. In several animals, with use of the syn-

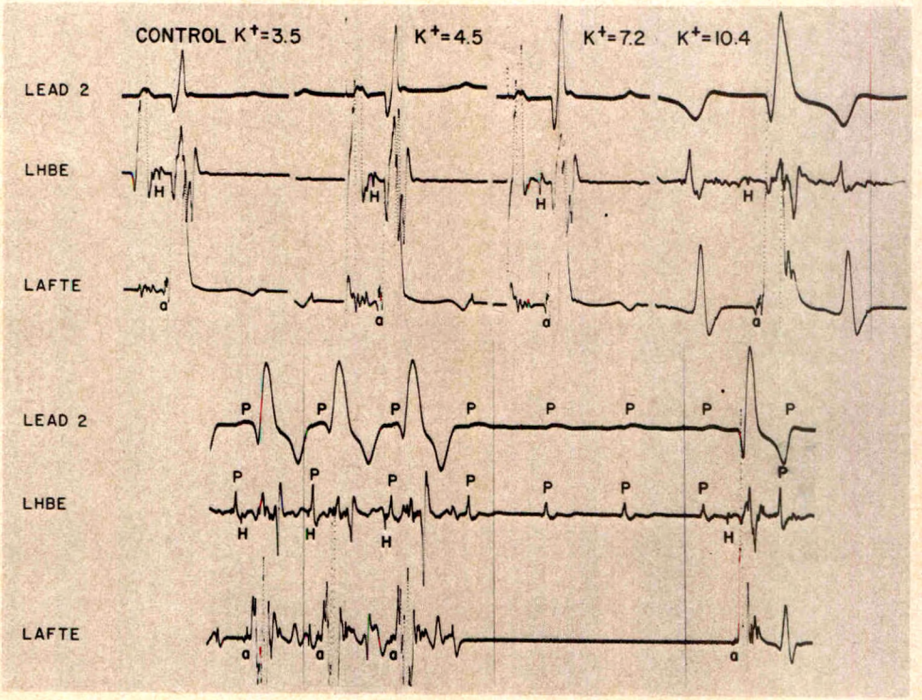

FIGURE 3. Top, rapid increase in QRS duration and H–Q interval as plasma K^+ increases across a critical range from 7.2 to 10.4 mEq/liter. His bundle (H) and anterior false tendon (a) impulses precede each QRS complex. The P–R segment lengthens progressively and the P wave diminishes in amplitude. **Bottom,** at K^+ level of 10.4 mEq/liter. Dissociation between the P and H complexes is now present. QRS complexes occur irregularly but each is preceded by H and a impulses. A–V junctional block is present and the ventricles are activated by an irregular, accelerated junctional mechanism. The last QRS complex may be conducted from the preceding P wave.

chronizing mode of the pacemaker, a ventricular stimulus impulse of twice diastolic threshold was gradually allowed to approach the T wave of the previous normal beat until it failed to produce an extrasystole, in an effort to induce a repetitive ventricular response.[12]

In all animals blood hematocrit and pH were normal in the control state. Duplicate samples of arterial and coronary sinus blood were drawn, pressures or electrical events, or both, measured, and an infusion of isotonic potassium chloride into the inferior vena cava was begun at rates of 12 or 24 cc (1.7 or 3.4 mEq)/min, depending upon the size of the animal. Blood drawn was replaced in equivalent amount from a donor animal. Electrical activity and hemodynamic variables were recorded and blood samples taken at increments of 4 to 8 minutes at first, and later at shorter intervals. These measurements and coronary blood flow determinations were subsequently correlated with plasma K^+ levels.

Studies were terminated by the development of asystole (28 animals) or ventricular fibrillation (2 animals). The hearts were quickly removed by thoracotomy (30 seconds) and placed in iced Ringers solution. Full thickness segments of free left ventricular wall from the left anterior descending and circumflex coronary arterial regions were removed and rapidly divided by sharp dissection into inner, middle and outer thirds and then frozen in liquid nitrogen and freezer-stored for subsequent analysis of water, K^+ and Na^+ [13] content. Tissue water was determined by weight difference before and after oven drying of a tissue homogenate overnight at 110° C.

Statistical analyses were performed by computer using standard techniques for small samples. Means were compared using Student's *t* test, unpaired when evaluating tissue changes in hyperkalemic and normal animals and paired when comparing electrical changes in the hyperkalemic animals.

Results

Electrophysiologic changes: As noted by prior investigators,[14,15] hyperkalemia initially became manifest by peaking of T waves and shortening of the $Q–T_c$ interval. Heart rate tended to slow during infusion, although this was somewhat variable in different animals. P waves became reduced in amplitude until they could not be seen in the peripheral electrocardiogram at K^+ levels of 8 to 10 mEq/liter; at these levels the ventricular response generally became irregular, at times with Wenckebach periodicity, but invariably with His bundle and bundle branch impulses preceding each QRS complex (Fig. 1).

His–Q and QRS durations increased rapidly at higher levels of K^+ (Fig. 2, Table I). In several animals the His–Q interval shortened by 10 to 15 percent at K^+ levels of 5 to 7 mEq/liter or more; this change was not accompanied by a measurable change in the QRS complex. His–Q and QRS durations remained relatively stable until levels of K^+ greater than 8 to 9 mEq/liter were reached, after which both increased rapidly. The His complex itself became wider, more slurred and of lower amplitude. The QRS complex became first widened, then distorted as hyperkalemia progressed (Fig. 3). In addition, block at the A–V nodal level frequently became evident at K^+ levels of ≥10 mEq/liter, with dissociation of atrial and ventricular complexes, the latter always preceded by His and bundle branch impulses.

Increases observed in the H–Q and in H–a intervals were of similar degree initially, but block distal to the bundle branch recording site became evident

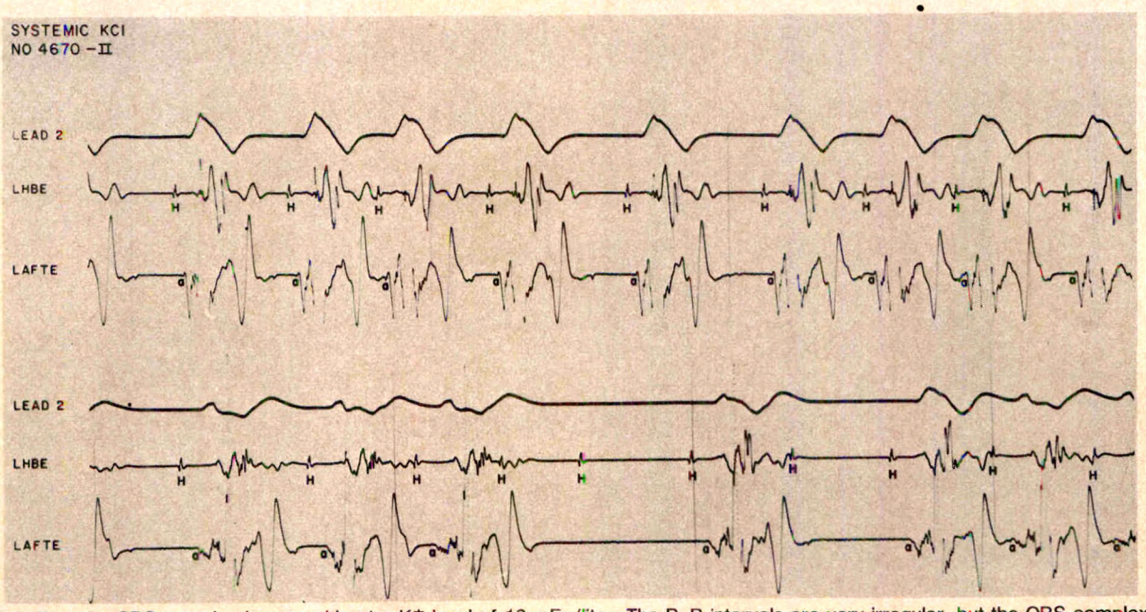

FIGURE 4. Top, the QRS complex is very wide at a K^+ level of 12 mEq/liter. The R–R intervals are very irregular, but the QRS complex is obviously of supraventricular origin since an H deflection precedes each. Bundle branch impulses are present but poorly seen because of slowing and reduction of amplitude. **Bottom,** slightly later. Gross distortion of the QRS complex is seen. The first five (H) impulses occur progressively earlier, suggesting a possible Wenckebach phenomenon, but the subsequent H impulses are not regular enough to verify this possibility. Block within the His-Purkinje system is demonstrated by failure of the fourth, fifth and seventh His impulses to be conducted to the ventricles. Bundle branch impulses are not well seen.

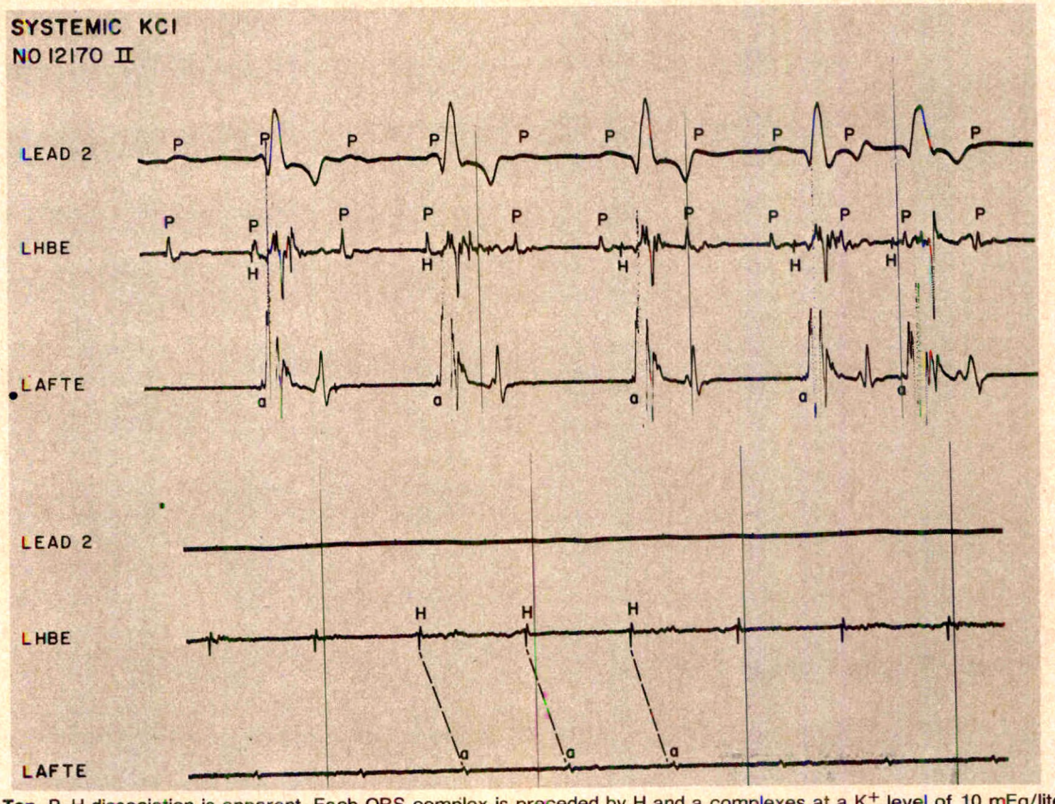

FIGURE 5. Top, P–H dissociation is apparent. Each QRS complex is preceded by H and a complexes at a K^+ level of 10 mEq/liter. **Bottom,** 1 minute later, asystole is seen on the peripheral electrocardiogram although H impulses continue to be generated and regularly conducted to (or possibly through) the bundle branch recording site. This technique cannot distinguish between block in the distal Purkinje system or at the Purkinje-muscle junction. Paper speed = 100 mm/sec in both panels.

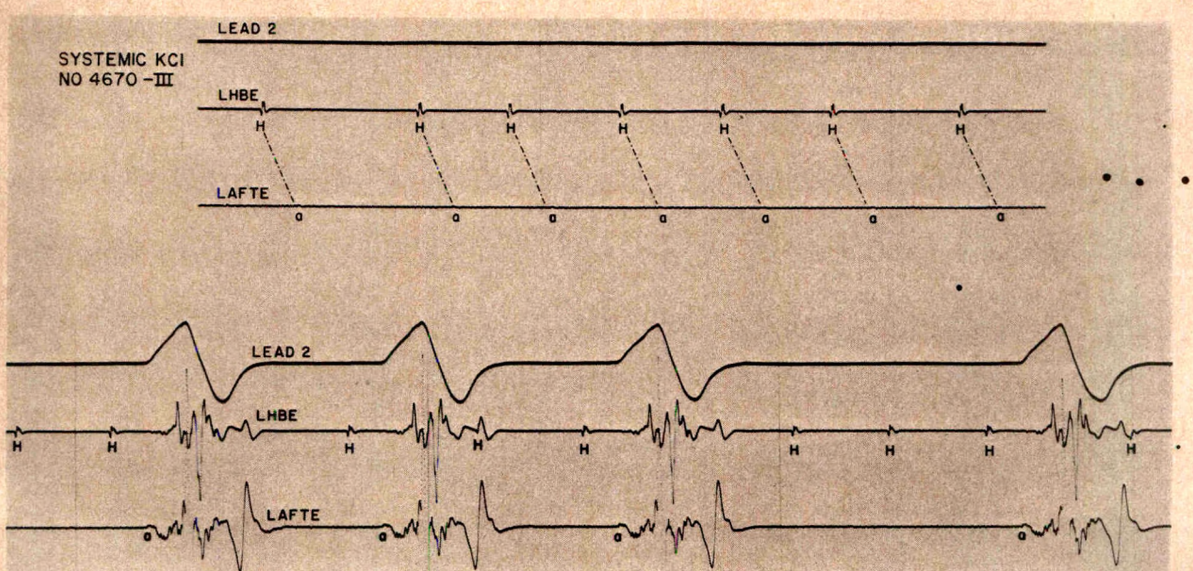

FIGURE 6. Top, at asystole. Conduction impulses continue to be irregularly generated and transmitted from the His bundle to the bundle branches. **Bottom,** a few seconds later. The QRS complex reappears, greatly widened, despite continuation of infusion. Since each QRS complex is preceded by an H complex at a constant interval, it is conducted from above, probably from the A–V junctional region. Further slurring of the H and QRS complexes is evident.

in several animals at K^+ levels of 10 to 12 mEq/liter, when the ventricular rhythm became more regular, with very wide, slurred QRS complexes, and each QRS complex was at first preceded by a delayed and slurred His complex and a bundle branch complex. Some unusual sequences then developed (Fig. 4), indicating block below the His bundle in the distal conduction system. Asystole sometimes developed suddenly as a result of terminal Purkinje or Purkinje-muscle block (Fig. 5 and 6). Although peripheral electrocardiographic activity ceased, impulses traveling from the His bundle to a bundle branch were demonstrated. The terminal rhythm was asystole in 28 or 30 animals; 2 animals died suddenly with ventricular fibrillation.

A rapid rhythm with a wide QRS complex began suddenly in two experiments at very high levels of K^+ (Fig. 7). Although this rhythm was apparently ventricular tachycardia, widening and fusion of the QRS–T complexes prevented accurate assessment of the rhythm by the His bundle technique. This rhythm resembled that described by Vassalle et al.[16] and Cohen at al.[17] as ventricular flutter.

At terminus, the mean arterial and coronary sinus plasma K^+ levels were 12.4 and 11.5 mEq/liter, respectively. This difference was not statistically significant.

Hemodynamic changes: Left ventricular systolic pressures remained unchanged until plasma K^+ reached levels inducing asystole (Table II). Left ventricular end-diastolic pressure increased consistently in every animal even with modest increases in K^+. Since ventricular volume was not measured, it is uncertain whether this increase was due primarily to diminished ventricular function or to increased preload and/or reduced compliance, or both. Left ventricular dP/dt max decreased significantly at a K^+ level greater than 11 mEq/liter. Mean coronary blood flow did not change significantly in six animals studied; ischemia was not present in any experiment.

Intramural electrocardiographic changes: As hyperkalemia progressed, the absolute height and rate of rise (dV/dt max) of the intramural electrograms decreased (Fig. 8). The time from endocardial to epicardial activation progressively increased as well, all indicating slowed conduction through the ventricular wall. Table I summarizes the intramural electrophysiologic changes during hyperkalemia. As the QRS complex increased, the $Q–T_c$ component of the QRS complex did not change significantly, indicating a net shortening of $Q–T_c$ relative to the QRS complex (decline in $|Q\text{-}T_c–QRS|$). Voltage reduction to approximately 41 percent of the control level occurred in both endocardium and epicardium, with a

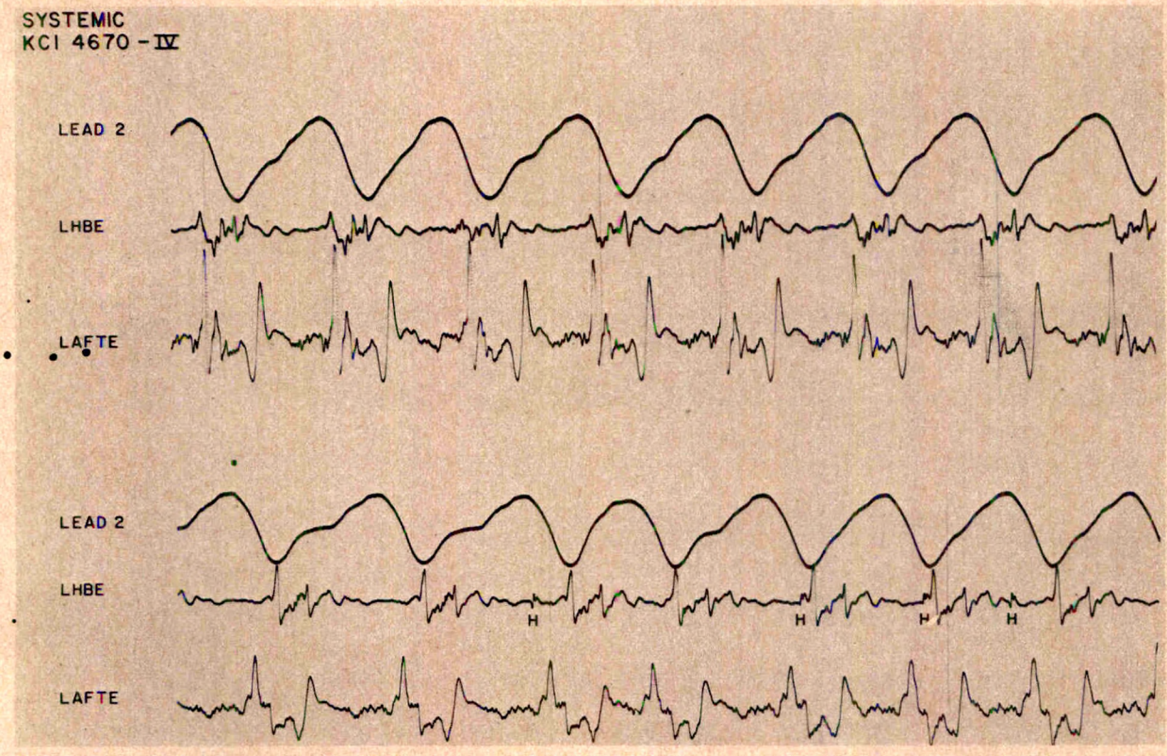

FIGURE 7. Top, the rapid, regular and wide QRS complex suggests ventricular tachycardia. Continuous electrical activity defies analysis by the electrode catheter technique. **Bottom,** a more irregular section uncovers apparent H complexes, but the irregularly appearing His activation bears no obvious relation to the QRS complex. Ventricular tachycardia remains the most likely possibility. This rhythm was rarely seen, and only at a K^+ level greater than 10 mEq/liter.

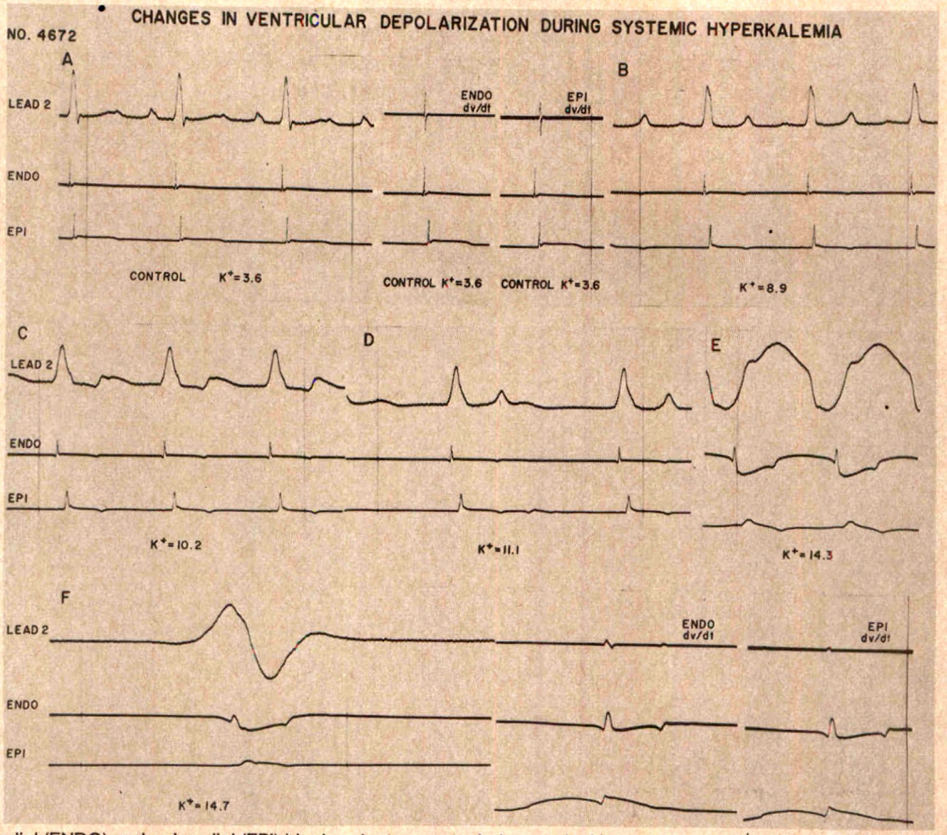

FIGURE 8. Endocardial (ENDO) and epicardial (EPI) bipolar electrograms during gradual hyperkalemia. K^+ concentration during each recording is indicated. Electrographic spike height and maximal rate of rise (dV/dt) progressively decline until pronounced slurring is evident **(E, F).** Endocardial and epicardial sites are affected to a similar degree and the Q–T interval at each location is also similar, correlating with the homogeneous increments of tissue K^+ observed in outer and inner wall layers. From the time electrograms were recorded in **F** to the time dV/dt values were recorded, the temporal relation between endo- and epicardial activation changed, implying a late change in activation sequence.

similar shortening of electrographic Q–T_c interval by approximately 15 percent in each. Transmural conduction time increased by 150 percent. DV/dt max was measured in three animals and declined in all to a similar degree in outer and inner layers.

Altered ventricular excitability was determined by endocardial and epicardial pacing thresholds during hyperkalemia (Fig. 9). Pacing thresholds remained constant until the K^+ level was 9 mEq/liter, after which they increased rapidly. After conduction block had induced asystole, ventricular pacing in several animals maintained cardiac contraction.

Early premature ventricular beats were induced to evaluate the possibility that conduction slowing might allow reentry to occur or that increased excitability would be "unmasked." Neither phenomenon was observed.

Myocardial water and electrolyte content: Values for left ventricular tissue water (percent of wet weight), K^+ and Na^+ (μEq/g wet weight) were determined in 21 hyperkalemic dogs at asystole and compared with values in 6 normal dogs studied in this laboratory (Table III). Data presented are from the outer, middle and inner thirds of a full thickness segment from the region of the left anterior descending coronary artery. The circumflex arterial area was also analyzed in 8 dogs and was of similar composition. Tissue water was unchanged. Myocardial electrolyte determination reflected a homogeneous increment of K^+ throughout the left ventricular wall, and myocardial Na^+ was similarly increased. These uniform increases paralleled the similar endocardial and epicardial electrical changes observed with the intramural leads.

Discussion

Hyperkalemia occurs in renal failure and may induce serious cardiac rhythm disturbances in this clinical setting. Yet potassium ion has been utilized for its antiarrhythmic properties,[18–27] although potentiation of digitalis-induced A–V block[28] and A–V block induced by increased extracellular K^+ alone at high concentrations[29] or during rapidly increasing extracellular K^+ levels in hypokalemia[14,30,31] may occur with hazard.[32–34] Hyperkalemic cardiac arrest was first observed experimentally by Hering in 1907.[35]

Conduction changes during hyperkalemia: Increased extracellular K^+ lowers myocardial resting membrane potential and shortens the action potential.[3,36] The latter induces Q–T_c shortening, which

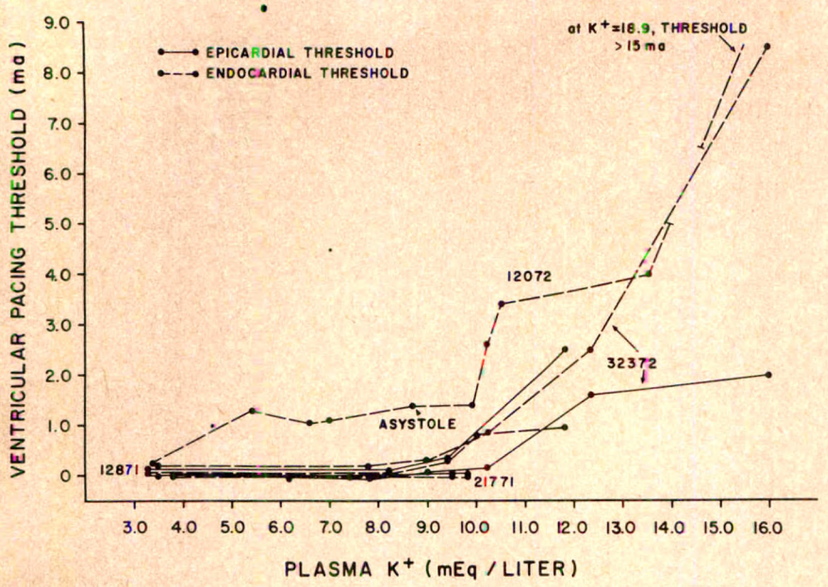

FIGURE 9. Epicardial and endocardial pacing thresholds during progressive hyperkalemia. Increases in threshold appeared similarly in both layers at a K^+ level of 9 to 10 mEq/liter and were continuous. Two animals underwent pacing for several minutes after spontaneous asystole had occurred (data in one are shown here). Asystole occurs because of failure of propagation of activation in the His-Purkinje system; the cardiac muscle is capable of continued contraction if sufficient electrical stimulus is applied.

was apparent after onset of infusion in our animals as in the study of Surawicz et al.[14] The Q–T_c interval prolonged only after the QRS complex had greatly widened. Despite QRS prolongation, it was apparent from our bipolar electrographic studies (Table I, Fig. 8) that local action potentials remained shortened even during severe hyperkalemia, thus indicating that QRS prolongation is a direct result of severe intraventricular conduction delay. Indeed, when the asystolic heart was removed from the hyperkalemic animal, slow rhythmic contractile waves began to traverse the ventricular surfaces in constant motion. The simultaneous presence of depolarization and repolarization processes during hyperkalemia was noted previously by Vassalle et al.[16]

We measured ventricular excitability by determination of endocardial and epicardial pacing thresholds during hyperkalemia. Several previous investigations have indicated a transient decrease in diastolic threshold at slightly elevated levels of K^+,[37–39] but another study[40] as well as our own failed to confirm this decline. Since depression of conduction may also account for changes in pacing threshold, the increased threshold observed at a K^+ level higher than 10 mEq/liter by ourselves and others may have been due in part to failure of local depolarization impulses to propagate.

The sequence of conduction changes as K^+ increased was usually reproducible. Flattening and disappearance of P waves occurred early. Disappearance of the P wave from the peripheral electrocardiogram does not imply loss of sinus activation[16] but is attributed to the differential effects of hyperkalemia upon atrial muscle and atrial conducting fibers.[41–43] After disappearance of the P wave, R–R intervals frequently became irregular. Sometimes typical Wenckebach periodicity of the QRS complex indicated progressive A–V nodal block (the H–Q interval was unchanged during the Wenckebach episode). Cohen et al.[17] demonstrated that loss of atrial conduction to the ventri-

cles occurred commonly during hyperkalemia. In their view, a junctional pacemaker was likely to be the origin of conducted beats at higher levels of K^+ since excess K^+ in man slows the primary pacemaker and accelerates subsidiary centers.[44] Atrial complexes recorded in several of our dogs showed dissociation between the atrial and the His bundle depolarizations, thus supporting this view (Fig. 3 and 5).

Asystole in hyperkalemia: The form of the QRS complex was at first similar to that of the control complex, thus indicating similar depolarization sequences. However, at K^+ levels greater than 10 mEq/liter, the QRS configuration usually changed suddenly when moderately widened, and local changes in the depolarization sequence within the myocardium were regularly observed near asystole (Fig. 8). Asystole was often associated with continued passage of conduction impulses down the Purkinje network. Mendez et al.[45] demonstrated in isolated canine Purkinje fiber-papillary muscle preparations that moderate increases of extracellular K^+ decreased conduction delay at this junction whereas higher concentrations increased it, and at K^+ levels of 10 to 11 mmoles/liter, total conduction block occurred. In our dogs, terminal Purkinje-muscle block may have occurred at slightly different times in different areas as plasma and tissue K^+ levels rose, thus accounting for the late morphologic changes in the QRS complex (changes in depolarization sequence) and, finally, asystole. The lesser sensitivity of ventricular Purkinje tissue to hyperkalemia compared with that of ventricular muscle was again demonstrated.

Myocardial contractility: Although increased extracellular K^+ reportedly diminished myocardial contractility in the isolated heart[46,47] as compared with the intact animal,[31,48,49] left ventricular dP/dt max at constant afterload (left ventricular systolic pressure did not fall) declined only at K^+ levels of more than 11 mEq/liter in our investigation. Left ventricular end-diastolic pressure increased progressively, contrary to the findings of Surawicz.[14] Failure of contractility to decrease until conduction alterations were pronounced suggested that the declining contractility at high K^+ levels may have been a result of the conduction changes that were occurring simultaneously.

Myocardial uptake and distribution of K^+: Myocardial K^+ uptake was uniform in different regions and transmurally, as demonstrated by tissue analysis, and similar homogeneous effects upon conduction were expected. As Table I indicates, reduction of action potential amplitude and duration (electrographic height and Q–T interval) were similar in inner and outer myocardial layers, contrasting with the heterogeneous electrical and ionic alterations observed during local intracoronary K^+ perfusion experiments in our laboratory, in which K^+ effects were significantly greater in epicardium than in endocardium.[4]

Localized cardiac hyperkalemia[4,50–54] results in S–T segment elevation and ventricular arrhythmias, the latter probably of reentrant origin.[4] S–T segment elevation was never observed in our experiments during systemic K^+ infusion, and ventricular extrasystoles were distinctly unusual. These findings suggest that homogeneity of conduction slowing eventuates in asystole and, conversely, that nonuniform conduction slowing tends to induce arrhythmias. Rapid systemic administration of a bolus injection of K^+ induces ventricular fibrillation as well as transient conduction disturbances, possibly because of initial lack of uniform distribution of this ion as it arrives in the heart.

Clinical implications: Since potassium rapidly depresses conduction at plasma levels in excess of 9 to 10 mEq/liter, minor reductions in K^+ by such expedients as glucose-insulin infusions may quickly restore conduction. Potassium salts may exert their antiarrhythmic effects by transient acceleration of conduction during modest hyperkalemia or by slowing of conduction at higher levels, either of which may interrupt a reentrant pathway. However, control of dosage is difficult and therapy hazardous when major conduction changes occur within such a narrow range of concentrations.

Acknowledgment

The technical assistance of Mrs. B. Jenkins, Mrs. L. Djeu, Miss R. Manno and Mrs. F. Herdman and the secretarial services rendered by Mrs. A. Binetti and Mrs. A. Brown are gratefully acknowledged. Intramyocardial electrode wires and technical advice were provided by Dr. B. Scherlag, Mt. Sinai Hospital, Miami Beach, Fla.

nitroglycerin is a notably unstable compound. It migrates from tablet to tablet, from tablet to cotton, from cotton to cap. Result: a wide variance in potency and therapeutic effect.

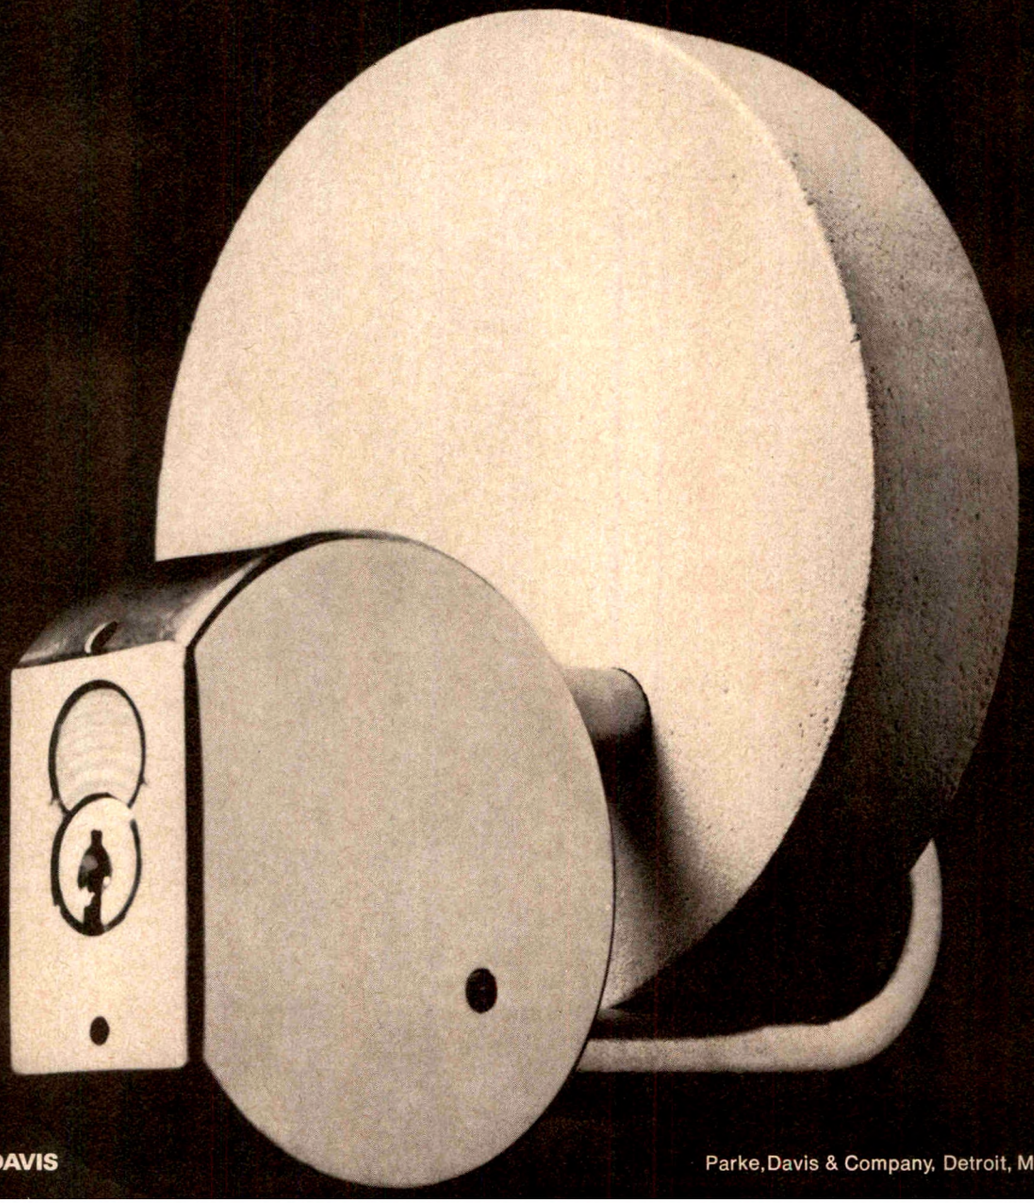
But with Nitrostat your angina patient gets a stabilized nitroglycerin. *Stabilized for uniform potency retention.* Thus, Nitrostat

glycerin is *supposed* to do. And does it *consistently*—providing the same pain-relieving potency, tablet after tablet. That's why more and more physicians are turning to Nitrostat.

Important facts to know whenever you're prescribing for a patient with a history of angina.

Nitrostat®
(nitroglycerin tablets, USP)
Sublingual Tablets
0.6 mg (1/100 gr)
0.4 mg (1/150 gr)
0.3 mg (1/200 gr)

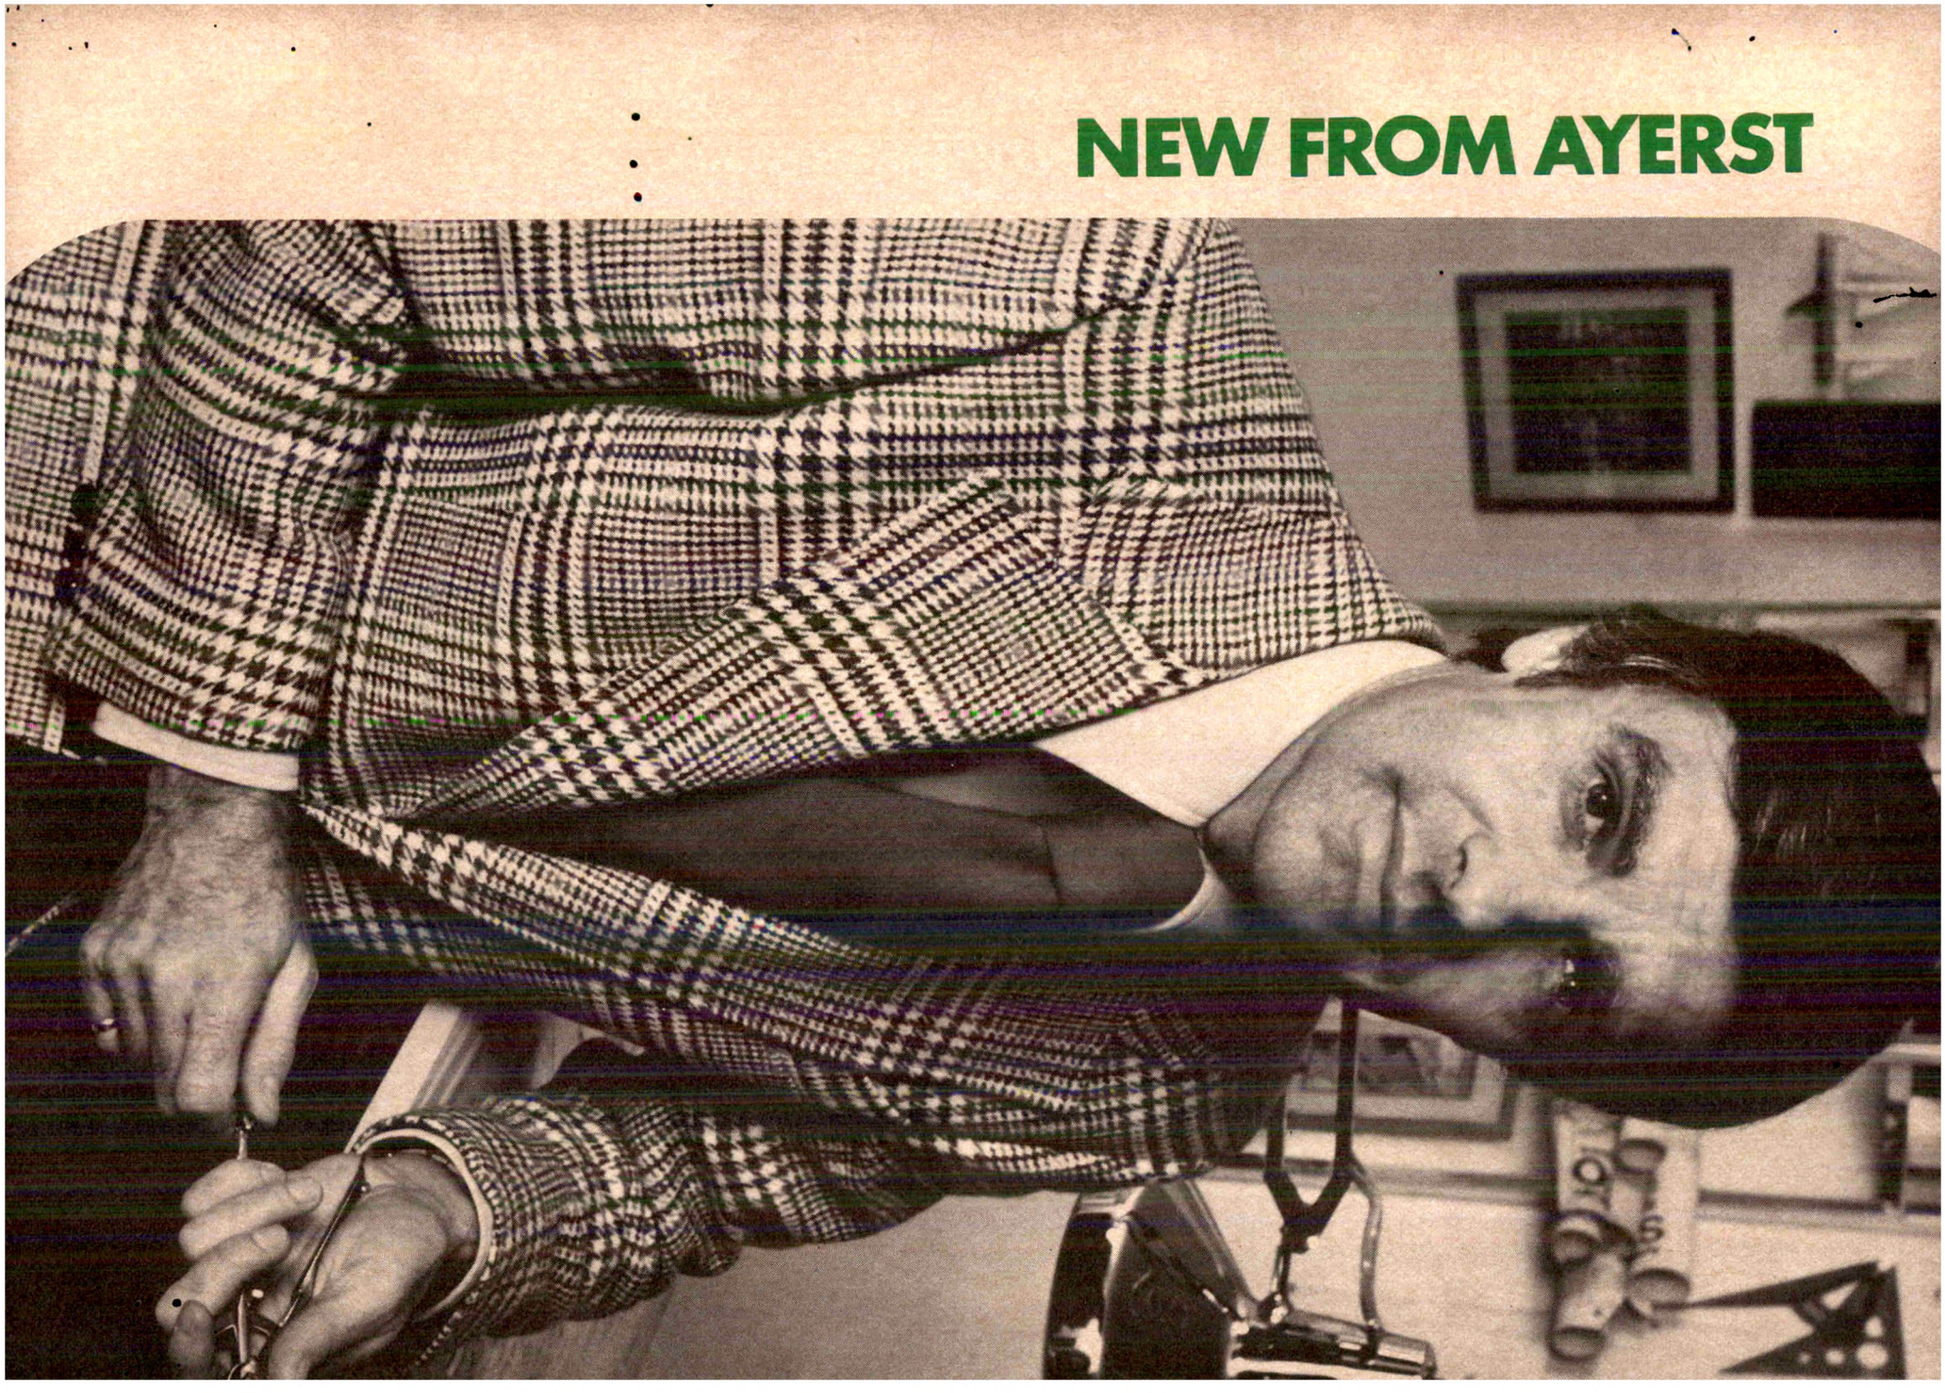
Because the pain-relieving potency is locked inside–this nitroglycerin tablet will work like the next–and the next–and the next.



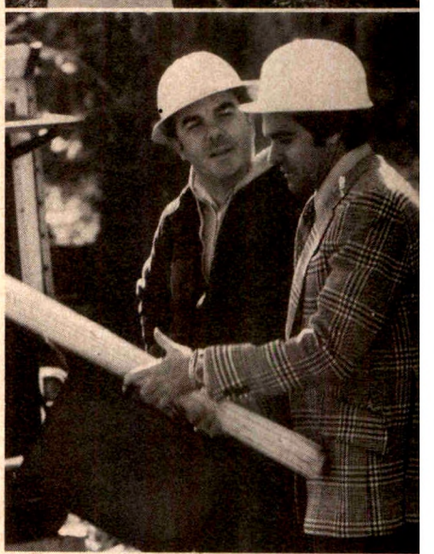
PARKE-DAVIS

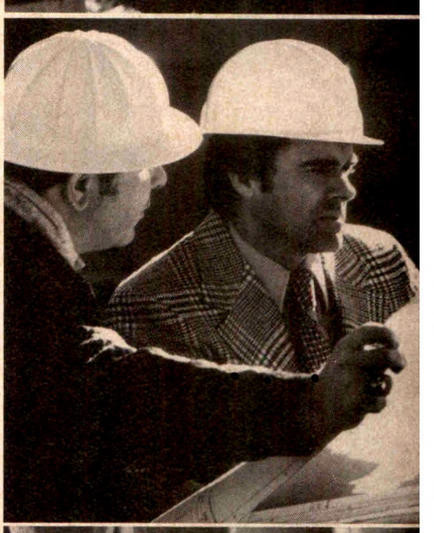
Parke, Davis & Company, Detroit, Michigan 48232

NEW FROM AYERST



the "healthy" hypertensive





It may be years before he experiences a single symptom of hypertension. But left untreated, even mild to moderate elevations of blood pressure may quietly strip years from an otherwise healthy and active life. Early control with DIUCARDIN may help forestall damage to healthy target organs.

DIUCARDIN provides approximately the same diuretic potency as hydrochlorothiazide at maximal therapeutic dosage. With DIUCARDIN, the onset of diuresis is gradual and may be maintained for twelve hours or more with a single dose.[1,2] The antihypertensive effect of DIUCARDIN is usually maintained in long term use. For many patients on DIUCARDIN, a convenient once-a-day dosage may suffice.

Based on efficacy *and* economy, DIUCARDIN provides a good beginning for many hypertensive patients. New DIUCARDIN 50 mg. Tablets. For mild to moderate hypertension and adjunctive therapy for many types of edema. Ayerst®

controlled early on

Diucardin® TABLETS

(hydroflumethiazide)

diuretic/antihypertensive

(See prescribing information on next page.)

NEW FROM AYERST

For the "healthy" hypertensive, early control with

Diucardin® TABLETS (hydroflumethiazide)

diuretic/antihypertensive

BRIEF SUMMARY

(For full prescribing information, see package circular.)

ACTIONS: The primary action of the thiazide diuretics is to produce diuresis by increasing the renal excretion of sodium and chloride. They inhibit the mechanism for tubular reabsorption of sodium and chloride by direct action on the distal segment. At maximal therapeutic dosage all thiazides are approximately equal in their diuretic potency.

The mechanism(s) of the antihypertensive action of the thiazides has not been elucidated.

INDICATIONS: **Hypertension:** DIUCARDIN alone may provide adequate control in mild or moderate hypertension. In severe hypertension or in cases of mild or moderate hypertension which do not respond adequately, DIUCARDIN may be used in conjunction with other antihypertensive agents.

DIUCARDIN alone or in conjunction with other antihypertensive agents is indicated for control of hypertension in pregnancy. (See WARNINGS)

Edema: DIUCARDIN is indicated as adjunctive therapy in edema associated with congestive heart failure, hepatic cirrhosis, and corticosteroid and estrogen therapy.

DIUCARDIN is indicated in severe edema during pregnancy. (See WARNINGS)

DIUCARDIN is indicated in the treatment of edema due to various forms of renal dysfunction, *e.g.* nephrotic syndrome, acute glomerulonephritis, and chronic renal failure.

CONTRAINDICATIONS: Anuria, oliguria. Hypersensitivity to DIUCARDIN or other sulfonamide derivatives.

The routine use of diuretics in an otherwise healthy pregnant woman with or without mild edema is contraindicated and possibly hazardous.

WARNINGS: Use with caution in severe renal disease since thiazides may precipitate azotemia. Effects due to accumulation of the drug may occur in patients with impaired renal function.

Use with caution in patients with impaired hepatic function or progressive liver disease since minor changes of fluid and electrolyte balance may precipitate hepatic coma.

Use with caution when hydroflumethiazide is administered in conjunction with other antihypertensive agents. Lowering of dosage of these agents is usually indicated. Thiazides potentiate ganglionic or peripheral adrenergic blocking drugs.

Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma.

The possibility of exacerbation or activation of systemic lupus erythematosus has been reported.

Usage in Pregnancy and During Lactation: Thiazides cross the placental barrier and also appear in breast milk. Consequently, they may cause fetal or neonatal hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism and other adverse reactions. Therefore, the potential benefits of thiazide administration in women of childbearing age must be weighed against the possible hazards to the fetus or child.

PRECAUTIONS: Tests should be made at appropriate intervals to detect possible electrolyte imbalance, *i.e.* hypokalemia, hyponatremia, and hypochloremic alkalosis. All patients taking thiazides should be observed for signs and symptoms of electrolyte or fluid imbalance, namely dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting. Serum and urine electrolyte determinations are particularly important if the patient is vomiting excessively or receiving parenteral fluids.

If hypokalemia should develop, dietary potassium supplementation or the use of dilute potassium solutions should be tried. Small bowel lesions have been reported following the administration of enteric coated, concentrated preparations of potassium salts.

Dilutional hyponatremia may occur in edematous patients during hot weather. Water restriction rather than administration of salt is appropriate except in rare cases when hyponatremia is life-threatening. In actual salt depletion, appropriate replacement should be given.

Hypochloremia is generally mild and usually does not require specific treatment except under extraordinary circumstances, as in renal or liver disease.

The possibility of development of electrolyte or fluid imbalance is increased by brisk diuresis, severe liver disease, or concomitant administration of medications such as digitalis, ACTH, and corticosteroids.

Adequate oral intake of electrolytes should be maintained to minimize the possibility of electrolyte imbalance.

If a progressive increase in serum nitrogen occurs, a careful appraisal of the patient's condition should be made to determine whether diuretic therapy should be continued.

Because of the possibility of hypokalemia developing, patients taking digitalis should be followed carefully since a decrease in body potassium may necessitate lowering digitalis dosage.

Plasma uric acid levels may be increased and could, in susceptible patients, precipitate an attack of gout.

Thiazides alter carbohydrate metabolism. Patients who have diabetes mellitus or are suspected of being prediabetic should be followed closely since hyperglycemia and glycosuria may occur. Dosage adjustment of antidiabetic agents is frequently indicated.

Thiazides may decrease serum PBI without signs of thyroid disturbance.

Thiazides act to decrease the response of the peripheral arterial system to catecholamines and to enhance the effects of curare and its derivatives. Caution should be exercised in administering general anesthesia or curare derivatives to patients taking thiazides.

The antihypertensive effect of thiazides may be enhanced following sympathectomy.

ADVERSE REACTIONS: **Gastrointestinal:** anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, acute pancreatitis. **Central Nervous System:** dizziness, vertigo, headache, paresthesias, xanthopsia, restlessness.

Hematologic: leukopenia, thrombocytopenia, agranulocytosis, aplastic anemia.

Allergic: purpura, photosensitivity, rash, urticaria, necrotizing angiitis, exfoliative dermatitis, glomerulonephritis, intrahepatic cholestatic hepatitis.

Cardiovascular: orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics).

Musculoskeletal: muscle cramps, weakness.

Clinical Laboratory Test Findings: electrolyte imbalance, elevation of serum nitrogen, elevation of plasma uric acid, hyperglycemia and glycosuria, decreased serum PBI levels.

DOSAGE AND ADMINISTRATION: **Usual adult dosage:** 50-100 mg. per day.

The dosage regimen should be individualized to obtain the maximum effect at the lowest dosage level. Dosage regimens using 25 mg. DIUCARDIN (hydroflumethiazide) may be adequate in some cases. Dosage should not exceed 200 mg. per day.

HOW SUPPLIED: DIUCARDIN—No. 702—Each scored tablet contains 50 mg. hydroflumethiazide, in bottles of 100 and 1,000.

Model 5000 Dyna-Gram® Recorder

The Model 5000 Dyna-Gram® Recorder for Holter Electrocardiography.

The Model 5000 is a new 24-hour cassette recorder with electronic timing and a digital patient clock for precise correlation of the ECG with patient activities and symptoms. The advanced design of the Model 5000 includes an exclusive circuit to minimize electrode artifact. The rechargeable Dyna-Gram® Power-Pack provides continuous 24-hour recording capability *without* turning the cassette. Compact and light weight, the Model 5000 Dyna-Gram® Recorder can be worn with a waist belt or a shoulder strap.

No purchase of costly processing equipment is required. Your recorded Dyna-Gram® cassettes will receive Cardio-Dynamics comprehensive analysis using the unique Dyna-Gram® III Analyzer System.

A quality line of cassettes, disposable electrodes, and related patient hookup supplies is available.

HEMODYNAMICS OF ANGINA PECTORIS* — PATIENTS RESTING AND EXERCISING, BEFORE AND AFTER ISORDIL® SUBLINGUAL
(isosorbide dinitrate)

BEFORE MEDICATION		AFTER 5 mg. ISORDIL SUBLINGUAL (isosorbide dinitrate)
	PULMONARY ARTERY (MEAN PRESSURE)		TOTAL PULMONARY RESISTANCE		CARDIAC INDEX		BRACHIAL ARTERY (MEAN PRESSURE)		TOTAL SYSTEMIC RESISTANCE	
IN ANGINA PECTORIS*

- to abort or terminate acute anginal attacks
- to reduce the frequency and severity of anginal episodes often caused by unavoidable everyday stress

ISORDIL® SUBLINGUAL
(ISOSORBIDE DINITRATE)

SUBLINGUAL TABLETS: 2.5 mg. and 5 mg.

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows:
"Probably" effective: When taken by the sublingual route, Isordil Sublingual is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

A WELL DOCUMENTED DILEMMA:

Hidden Potassium Depletion And Associated Problems

"Hypokalemia is generally an indication of total body potassium depletion but cannot be used to predict the extent of depletion."

Vanamee P, Scheiner E. Fluid and Electrolyte Management in Adults. *Current Therapy* 1973. Conn H (ed). Philadelphia. W.B. Saunders Company. 1973. p 433.

"Negative total body potassium balance with hypokalemia is a characteristic effect of all thiazide diuretics."

Chrysant SG, Frohlich ED. Side effects of antihypertensive drugs. *Amer Fam Physician GP* 9:94-101 (Jan) 1974.

a simple answer to the hidden potassium dilemma

K+LORVESS®

effervescent tablets

Each tablet contains 20 mEq. each of potassium and chloride supplied by potassium chloride 1.125 g., potassium bicarbonate 0.5 g., L-lysine hydrochloride 0.913 g.

THE BALANCED BENEFIT
POTASSIUM AND CHLORIDE SUPPLEMENT
1:1 ratio K^+ and Cl^- in solution

GOOD TASTING KLORVESS OFFERS WHAT YOU AND YOUR PATIENT WANT: CONVENIENT POTASSIUM SUPPLEMENTATION WITH NO EXTRA CALORIES

- SIMPLE TO TAKE—Tablets dissolve in 3-4 oz. cold water
- EFFERVESCENT SOLUTION—Reduces chance of G.I. irritation.
- UNIT DOSE CONVENIENCE—Tablets individually foil wrapped

KLORVESS®
effervescent tablets

Description: Each dry effervescent tablet contains 20 mEq. each of potassium and chloride supplied by potassium chloride 1.125 g., potassium bicarbonate 0.5 g., L-lysine hydrochloride 0.913 g. Solution of the tablet in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate, and L-lysine hydrochloride.

Indications: For prevention or correction of potassium depletion and hypokalemic alkalosis. Especially useful when thiazide diuretics or corticosteroids cause excessive excretory potassium losses.

Contraindications: Severe renal impairment with oliguria or azotemia, untreated Addison's disease, adynamia episodica hereditaria, acute dehydration, heat cramps, and hyperkalemia from any cause.

Precautions: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. With normal kidney function, it is difficult, therefore, to produce potassium intoxication by oral administration. However, potassium supplements must be administered with caution, since the amount of the deficiency or daily dosage is not accurately known. Frequent checks of the clinical status of the patient, and periodic ECG and/or serum potassium levels should be made. High serum concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. This drug should be used with caution in the presence of cardiac disease. Potassium supplements should be given cautiously to digitalized patients. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, patients should be carefully directed to dissolve each tablet completely in the stated amount of water.

Adverse Reactions: Vomiting, diarrhea, nausea and abdominal discomfort may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias of the extremities, flaccid paralysis, listlessness, mental confusion, weakness and heaviness of the legs, fall in blood pressure, cardiac arrhythmias and heart block. Hyperkalemia may exhibit the following electrocardiographic abnormalities: disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, and tall, peaked T waves.

Dosage and Administration: Adults: 1 tablet (20 mEq. each of potassium and chloride) completely dissolved in 3 to 4 ounces of cold water 2 to 4 times daily depending upon the requirements of the patient. The approximate minimum adult daily requirement of potassium is 40 mEq. Deviations from this recommendation may be indicated, since no average total daily dose can be defined but must be governed by close observation for clinical effects. **NOTE: Klorvess should be taken with meals.**

Overdosage: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under Contraindications. Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

Treatment of Hyperkalemia:

1. Dextrose solution, 10 or 25% containing 10 units of crystalline insulin per 20 g. dextrose, given I.V. in a dose of 300 to 500 ml. in an hour.
2. Adsorption and exchange of potassium using sodium or ammonium cycle cation exchange resin, orally and as retention enema. (Caution: Ammonium compounds should not be used in patients with hepatic cirrhosis.)
3. Hemodialysis and peritoneal dialysis.
4. The use of potassium-containing foods or medicaments must be eliminated.

In cases of digitalization, too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

How Supplied: 60 Tablets (2 Rx Units of 30 effervescent tablets each). Each tablet is individually foil wrapped.

If only patients would confess.

Your low-sodium patients may not be telling all. It's not that easy to confess to their doctor that, in actuality, they're letting salt sneak back into their diets.

Cravings & rationalizations.

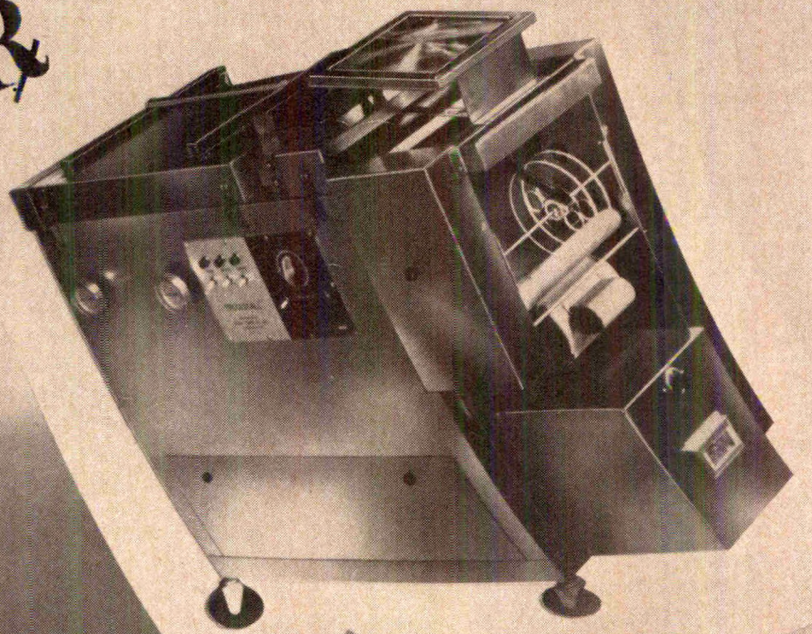
But the blandness of the low-sodium diet may have been more than they could stand, over time. So they summon their healthy powers of rationalization—with unhealthy results.

You might avert these lapses by suggesting, at the start, Adolph's Salt Substitute. It's America's best-selling brand—perhaps because it's the best tasting way to enhance the natural flavors of food. It can improve your patients' zest for eating. And reduce confessions.

Added benefits: Adolph's can be used in cooking just like ordinary salt. It's also a source of supplemental potassium.

Samples? Please write: Jeannette Frank, c/o Adolph's Ltd., Box 828, Dept. SM, Burbank, California 91503.

Processall gives you two keys to accurate diagnosis in Cine Fluorography.



High quality results. Fast processing.

In cine fluorography, you want fast results — but not at the price of fuzzy film detail. The Processall gives you fine grain yield, superior resolution for a sharp image and all the detail you need for an accurate diagnosis. With automatic processing and speeds up to 8 feet per minute, you get results fast.

Daylight-operated and self-threading, Processall was designed for maximum reliability and ease of operation. No special training is needed to get professional results. Compact, portable Processall fits almost anywhere.

A simple drive system and 316L stainless steel construction ensure complete reliability, long life, and minimum maintenance. Processall is designed for flawless high quality results. It includes a turbulent agitation processing technique, thermostatic control of solution temperature and an air impingement squeegee that removes moisture before the film or paper enters the turbulent heated air drying chamber. A positive drive, with a demand drive guarantees positive tracking. Electrocardiograph paper may also be processed.

No wonder major medical centers and hospitals are now using Processall. For more information contact us, or your nearest Oscar Fisher dealer.

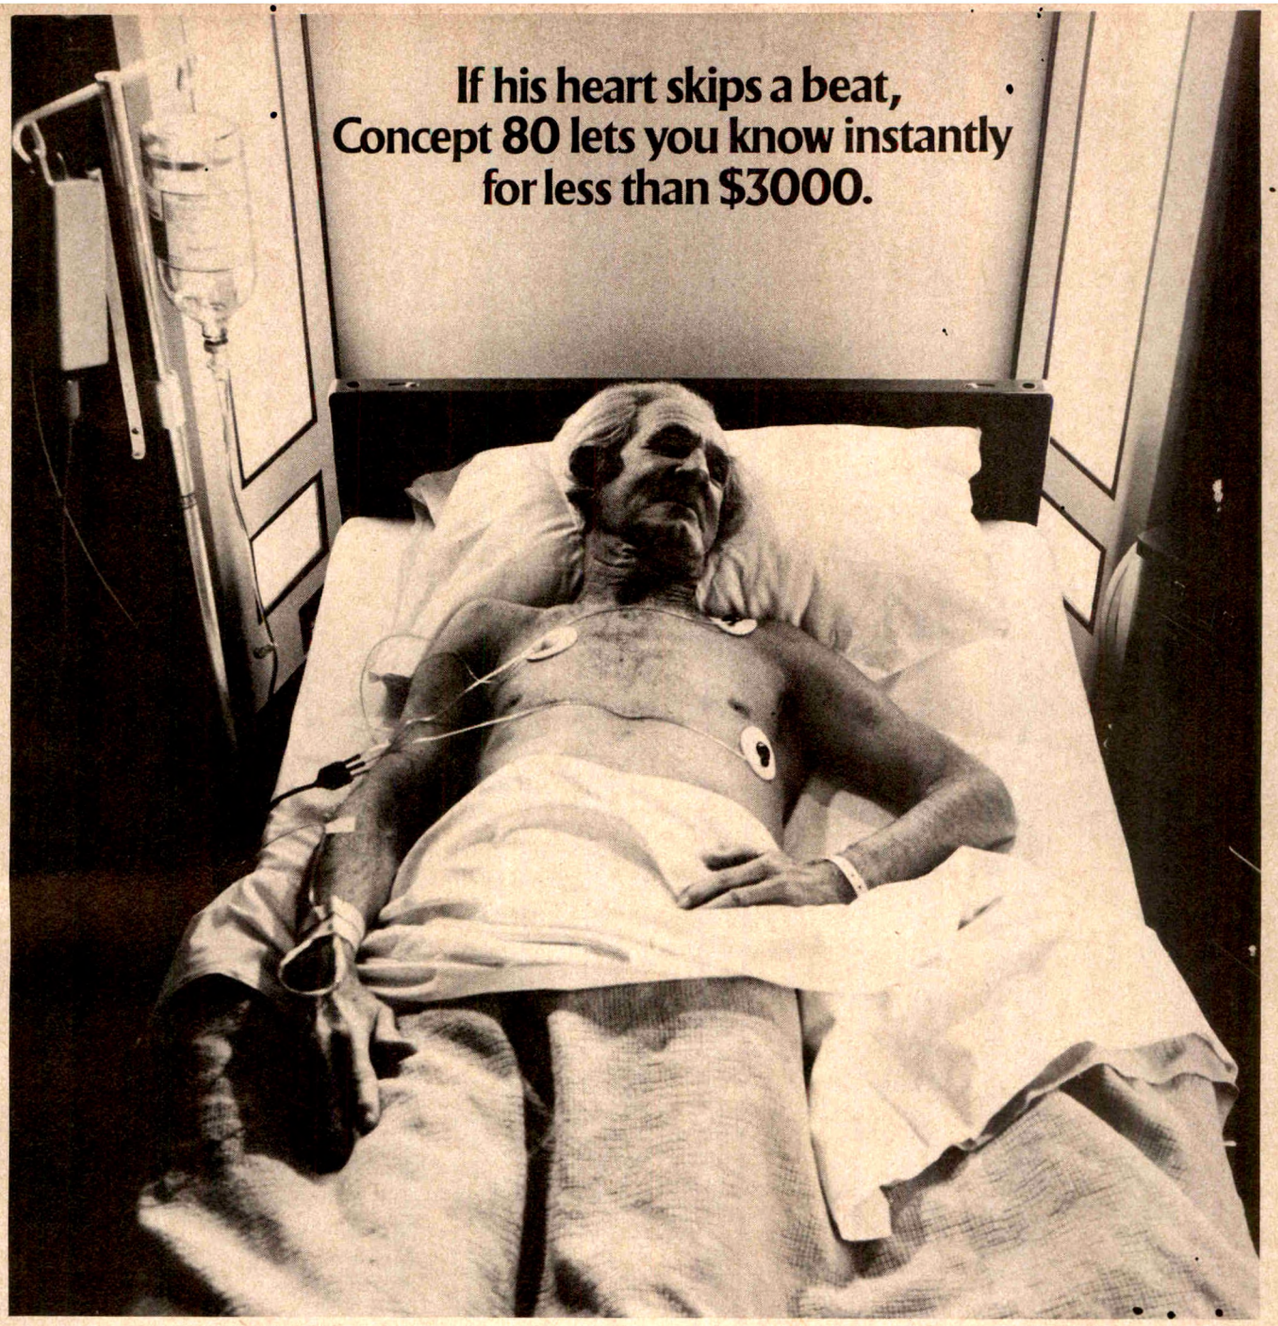
If his heart skips a beat, Concept 80 lets you know instantly for less than $3000.



A nurse can't watch the monitor every minute of the day. But with Concept 80, it isn't necessary. Unlike other cardiac monitoring systems it offers arrythmia recognition at every bed. And it's the only one that does it for less than $3000 a bed.

This early warning system is triggered by any cardiac irregularity exceeding a preset limit.

Plus Concept 80 is the only system that lets a nurse move around. Any change of a heart beat sets off an alarm at her station. A red light flashes, a chime sounds. The nurse automatically receives an immediate EKG reading. So in seconds, the nature of the problem can be determined.

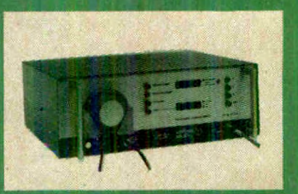
This lifesaving system is composed of five bedside units and a console which can be expanded to monitor up to 20 patients simultaneously. Concept 80's modular construction is easily connected to your existing equipment.

The system is available with either isolated preamplifier at bedside, or FCC approved telemetry for ambulatory patients. With this flexibility, you're able to offer more patients the kind of surveillance formerly reserved for intensive care and cardiac wards.

Concept 80. Now there's a cardiac monitoring system you can afford.

For more information, call Rex McLaughlin (714) 988-2557, or write Lockheed Concept 80, P.O. Box 33, Ontario, Ca. 91761. Lockheed offers immediate delivery.

Lockheed Concept 80



Vitatron Medical upgrade pacemaker reliability

Vitatron Medical now have upgraded the reliability of their pacemakers by application of a new HgO-Zn battery. This battery was specially designed for pacemakers and has a higher energy density and a better dependability.

Battery failure rate is no more than 0.05%/1000h. This new development, together with the battery switch reduces current consumption during transportation and storage to an absolute minimum, increasing pacemaker longevity by 50%.

The small dimensions, light weight, ideal shape and easy electrode connection make the new generation of Vitatron Medical pacemakers extremely easy to implant and assure a minimum of post-operative complications.

The unique intracardial electrode type MIP 2000 with means for fixation to the heartwall allows accurate placement of transvenous electrodes in more difficult cases.

Pacemaker follow-up reliability is achieved by Vitatron Medical's completely analysable pacing system consisting of the VCA pacemaker and the fully automized type MPA 1 digital pacemaker analyzer.

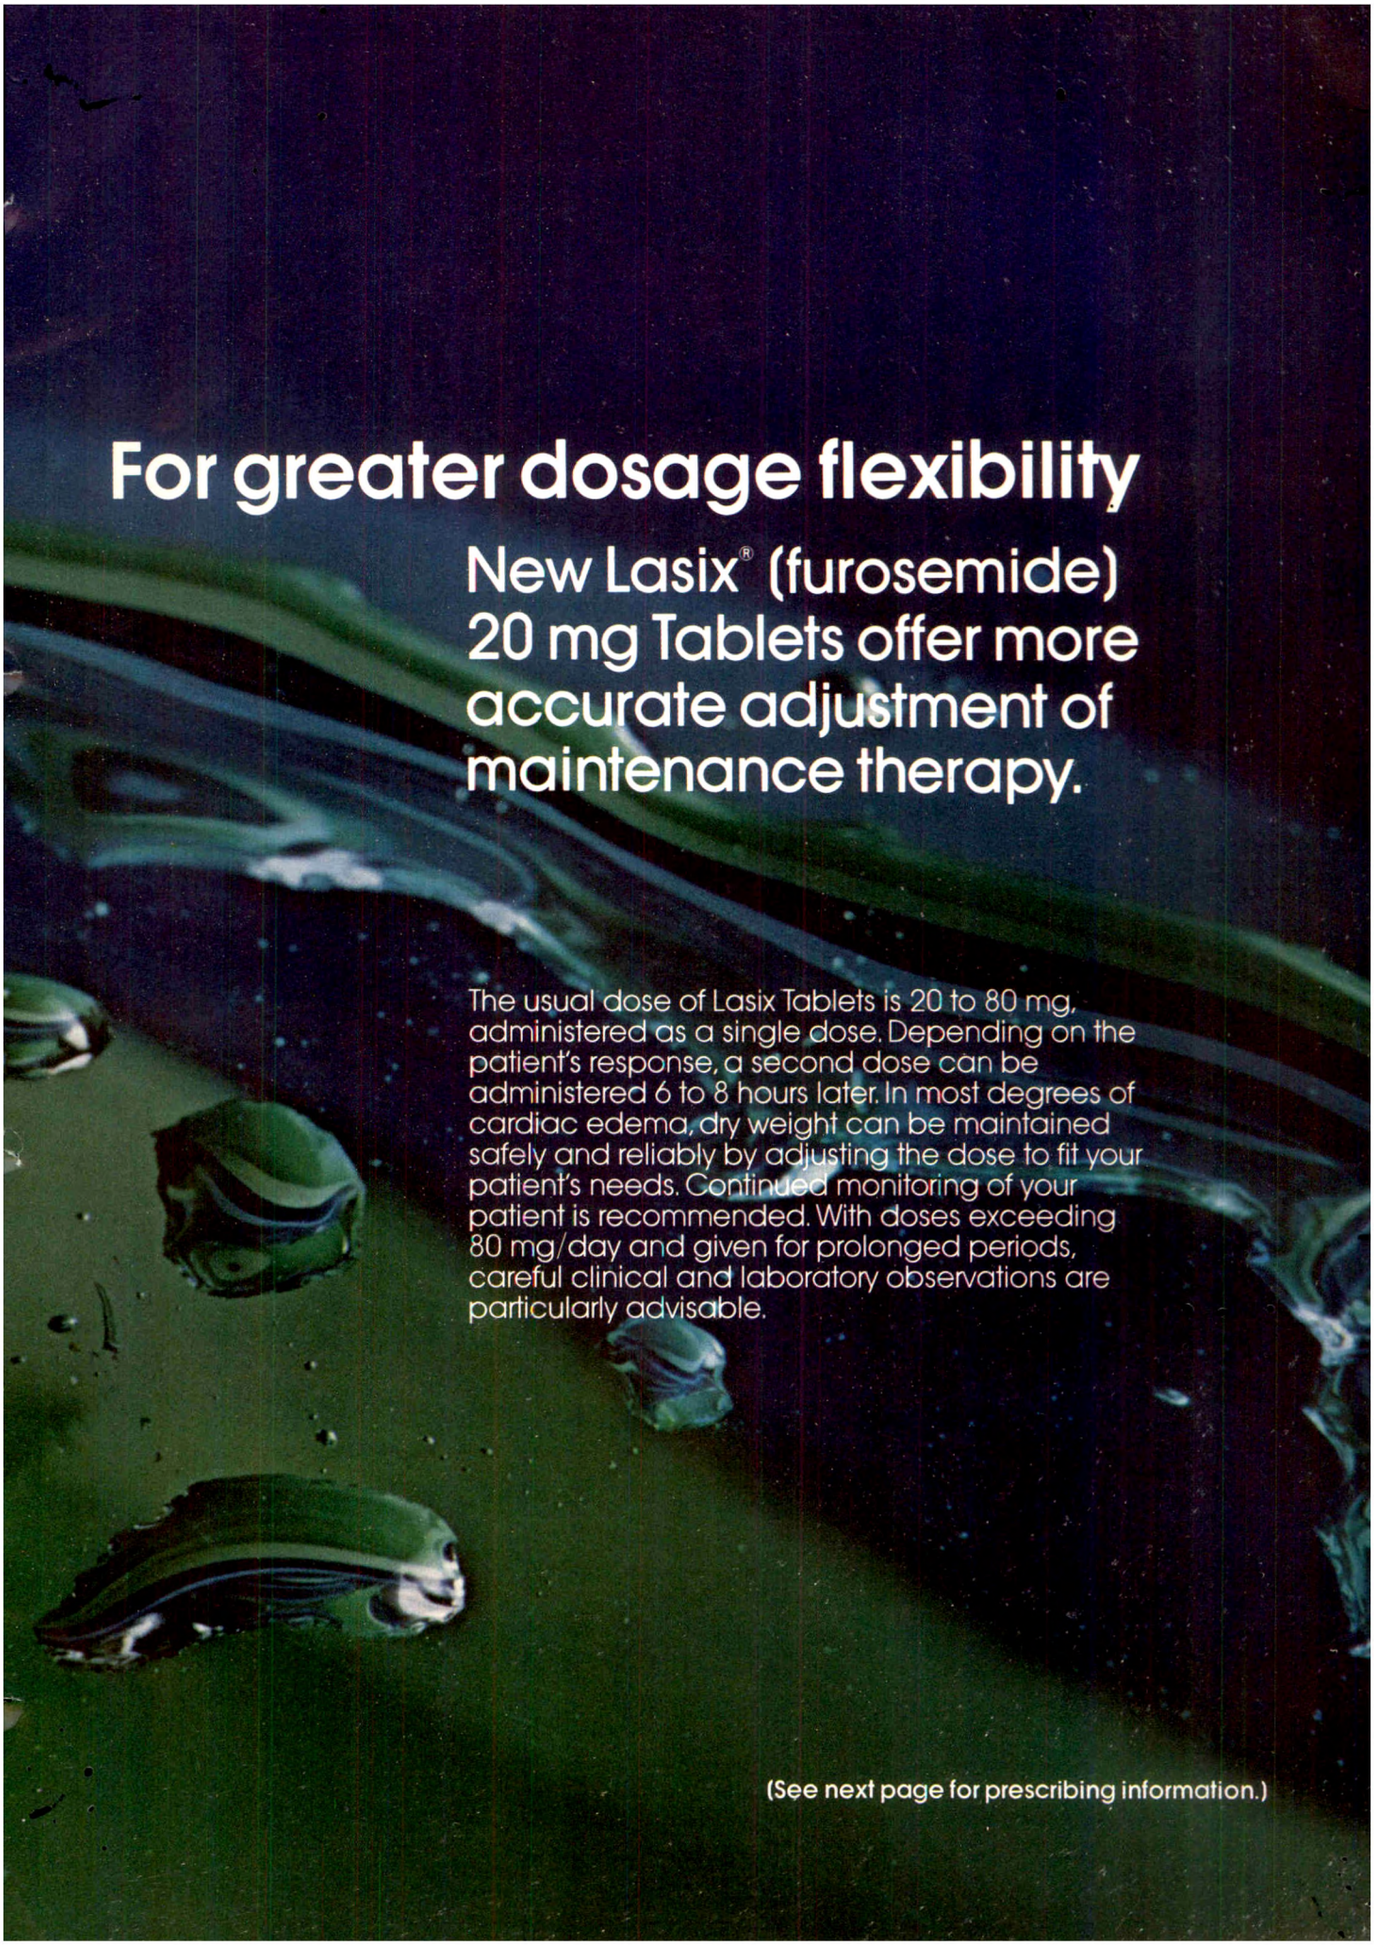
Tablets
(FUROSEMIDE)
For those stabilized
cardiac edema patients
who can be controlled
on a lower dosage
HOECHST
HOECHST
HOECHST



For greater dosage flexibility
New Lasix® (furosemide) 20 mg Tablets offer more accurate adjustment of maintenance therapy.
The usual dose of Lasix Tablets is 20 to 80 mg, administered as a single dose. Depending on the patient's response, a second dose can be administered 6 to 8 hours later. In most degrees of cardiac edema, dry weight can be maintained safely and reliably by adjusting the dose to fit your patient's needs. Continued monitoring of your patient is recommended. With doses exceeding 80 mg/day and given for prolonged periods, careful clinical and laboratory observations are particularly advisable.
(See next page for prescribing information.)

LASIX® 20 mg (FUROSEMIDE) and 40 mg Tablets

WARNING—Lasix® (furosemide) is a potent diuretic which if given in excessive amounts can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs. (See under "DOSAGE AND ADMINISTRATION.")

DESCRIPTION—Lasix is an anthranilic acid derivative. Chemically, it is 4-chloro-N-furfuryl-5-sulfamoylanthranilic acid.

INDICATIONS—Lasix is indicated for the treatment of the edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Lasix is particularly useful when an agent with greater diuretic potential than that of those commonly employed is desired.

Hypertension—Lasix Tablets may be used for the treatment of hypertension alone or in combination with other antihypertensive drugs. Hypertensive patients who cannot be adequately controlled with thiazides will probably also not be adequately controllable with Lasix alone.

CONTRAINDICATIONS—Because animal reproductive studies have shown that Lasix (furosemide) may cause fetal abnormalities, the drug is contraindicated in women of child-bearing potential.

Lasix is contraindicated in anuria. If increasing azotemia and oliguria occur during treatment of severe progressive renal disease, the drug should be discontinued. In hepatic coma and in states of electrolyte depletion, therapy should not be instituted until the basic condition is improved or corrected. Lasix is contraindicated in patients with a history of hypersensitivity to this compound.

Until more experience is accumulated in the pediatric use of Lasix, children should not be treated with the drug.

WARNINGS—Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Care should also be exercised in patients receiving potassium depleting steroids.

Frequent serum electrolyte, CO_2 and BUN determinations should be performed during the first few months of therapy and periodically thereafter, and abnormalities corrected or the drug temporarily withdrawn.

In patients with hepatic cirrhosis and ascites, initiation of therapy with Lasix (furosemide) is best carried out in the hospital. Sudden alterations of fluid and electrolyte balance in patients with cirrhosis may precipitate hepatic coma; therefore, strict observation is necessary during the period of diuresis. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis.

As with many other drugs, patients should be observed regularly for the possible occurrence of blood dyscrasias, liver damage, or other idiosyncratic reactions.

In those instances where potassium supplementation is required, coated potassium tablets should be used only when adequate dietary supplementation is not practical.

There have been several reports, published and unpublished, concerning nonspecific small-bowel lesions consisting of stenosis, with or without ulceration, associated with the administration of enteric-coated thiazides with potassium salts. These lesions may occur with enteric-coated potassium tablets alone or when they are used with nonenteric-coated thiazides, or certain other oral diuretics.

These small-bowel lesions have caused obstruction, hemorrhage, and perforation. Surgery was frequently required, and deaths have occurred.

Available information tends to implicate enteric-coated potassium salts, although lesions of this type also occur spontaneously. Therefore, coated potassium-containing formulations should be administered only when indicated, and should be discontinued immediately if abdominal pain, distention, nausea, vomiting, or gastrointestinal bleeding occurs.

Patients with known sulfonamide sensitivity may show allergic reactions to Lasix.

PRECAUTIONS—As with any potent diuretic, electrolyte depletion may occur during therapy with Lasix, especially in patients receiving higher doses and a restricted salt intake. Electrolyte depletion may manifest itself by weakness, dizziness, lethargy, leg cramps, anorexia, vomiting and/or mental confusion.

In edematous hypertensive patients being treated with antihypertensive agents, care should be taken to reduce the dose of these drugs when Lasix is administered, since Lasix potentiates the hypotensive effect of antihypertensive medications.

Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency.

When parenteral use of Lasix precedes its oral use, it should be kept in mind that cases of reversible deafness and tinnitus following the injection of Lasix have been reported. These adverse reactions occurred when Lasix was injected at doses exceeding several times the usual therapeutic dose of 20 to 40 mg.

Periodic checks on urine and blood glucose should be made in diabetics and even those suspected of latent diabetes when receiving Lasix. Increases in blood glucose, and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported.

Lasix (furosemide) may lower serum calcium levels, and rare cases of tetany have been reported. Accordingly, periodic serum calcium levels should be obtained.

Patients receiving high doses of salicylates, as in rheumatic diseases, in conjunction with Lasix may experience salicylate toxicity at lower doses because of competitive renal excretory sites.

It has been reported in the literature that diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, Lasix and cephaloridine should not be administered simultaneously.

Sulfonamide diuretics have been reported to decrease arterial responsiveness to pressor amines and to enhance the effect of tubocurarine. Great caution should be exercised in administering curare or its derivatives to patients undergoing therapy with Lasix, and it is advisable to discontinue Lasix for one week prior to any elective surgery.

ADVERSE REACTIONS—Various forms of dermatitis, including urticaria and rare cases of exfoliative dermatitis, erythema multiforme, pruritus, paresthesia, blurring of vision, postural hypotension, nausea, vomiting, or diarrhea, may occur.

Anemia, leukopenia, aplastic anemia, and thrombocytopenia (with purpura) may occur. Rare cases of agranulocytosis have occurred which responded to treatment.

In addition, the following rare adverse reactions have been reported; however, relationship to the drug has not been established with certainty: sweet taste, oral and gastric burning, paradoxical swelling, headache, jaundice, thrombophlebitis and emboli (see "WARNINGS"), and acute pancreatitis.

Lasix-induced diuresis may be accompanied by weakness, fatigue, lightheadedness or dizziness, muscle cramps, thirst, increased perspiration, urinary bladder spasm, and symptoms of urinary frequency.

As far as hyperglycemia is concerned, see "PRECAUTIONS."

DOSAGE AND ADMINISTRATION—The usual dose of Lasix is 20 to 80 mg given as a single dose, preferably in the morning. Ordinarily, a prompt diuresis ensues. Depending on the patient's response, a second dose can be administered 6 to 8 hours later. This dosage and dosage schedule can then be maintained or even reduced.

If the diuretic response with a single dose of 20 to 80 mg is not satisfactory; e.g., in a patient with congestive heart failure refractory to maximal doses of thiazides, the following schedules should be used: Increase this dose by increments of 20 or 40 mg not sooner than 6 to 8 hours after the previous dose until the desired diuretic effect has been obtained. This individually determined single dose should then be given once or twice daily (e.g., at 8:00 a.m. and 2:00 p.m.). The dose of Lasix may be carefully titrated up to 600 mg per day in those patients with severe clinical edematous states. Higher doses are currently under investigation.

The mobilization of edema may be most efficiently and safely accomplished by utilizing an intermittent dosage schedule in which the diuretic is given for 2 to 4 consecutive days each week. With doses exceeding 80 mg/day and given for prolonged periods, careful clinical and laboratory observations are particularly advisable.

Hypertension—The usual dose of Lasix is 40 mg twice daily both for initiation of therapy and for maintenance. Careful observations for changes in blood pressure must be made when this compound is used with other antihypertensive drugs, especially during initial therapy. The dosage of other agents must be reduced by at least 50 per cent as soon as Lasix is added to the regimen to prevent excessive drop in blood pressure. As the blood pressure falls under the potentiating effect of Lasix, a further reduction in dosage, or even discontinuation, of other antihypertensive drugs may be necessary. It is further recommended, if 40 mg twice daily does not lead to a clinically satisfactory response, to add other hypotensive agents; e.g., reserpine, rather than to increase the dose of Lasix.

Until more experience is accumulated in the pediatric use of Lasix, children should not be treated with the drug.

How Supplied—Lasix (furosemide) Tablets are supplied as white, monogrammed, scored tablets of 40 mg in amber bottles of 100 (NSN 6505-00-062-3336), 500 (NSN 6505-00-254-5546), and unit dose 100's (20 strips of 5) (NSN 6505-00-117-5982), and white, monogrammed, oval tablets of 20 mg in amber bottles of 100.

Note: Dispense in dark containers. Exposure to light may cause slight discoloration which, however, does not alter potency. PRINTED IN U. S. A. 5-74

Permanent Pervenous Transseptal Atrial Pacing

Canine Experiments and a Clinical Case

JOHN A. UDALL, MD, FACC

Irvine, California

Permanent atrial pacing has lain dormant during the last decade because pervenous electrodes usually fail to maintain endocardial contact, and epicardial electrodes require a thoracotomy for implantation. The major advantage is the preservation of synchronized atrioventricular (A–V) contractility. Development of a technique for attaching pacing electrodes to the endocardium through the venous system by an extrathoracic maneuver may permit achievement of reliable long-term atrial pacing pervenously. Canine experiments led to the first clinical application of atrial pacing by way of a transseptal electrode. A Ross needle was modified to carry a 10 mm T-shaped electrode tip across the atrial septum. An intraluminal stylet was used to eject the electrode into the left atrium. The electrode tip was then pulled snugly against the atrial septal endocardium. The hearts of 10 dogs were paced successfully for 3 to 12 months with average thresholds of 6 ma. At autopsy, various degrees of fibrosis constituted the sole pathologic finding. The heart of a 78 year old man with carotid sinus syncope was paced in August 1972, with use of a permanent transseptal atrial electrode and a unipolar pulse generator. The initial threshold was 2 ma and the pacemaker impulse–QRS interval was 180 msec. Consistent long-term atrial pacing may be achieved by attaching a pervenous electrode to the interatrial septum.

Permanent atrial pacing has rarely been used during the last decade because pervenous electrodes usually fail to maintain endocardial contact, and epicardial electrodes require thoracotomy for implantation. The indications have been presented comprehensively by De Sanctis,[1] and the major advantage is the preservation of synchronized atrioventricular (A–V) contraction in patients with cardiac insufficiency who require artificial pacing.

The attachment of pacing electrodes to the endocardium through the venous system by an extrathoracic maneuver is a new concept that invites the development of new techniques to achieve reliable long-term atrial pacing pervenously. A series of canine experiments led to the first clinical application of atrial pacing by the use of a transseptal electrode, both reported here.

Methods and Materials

The feasibility of pacing canine atria by attaching a barb-tipped electrode to the endocardium pervenously has been described earlier.[2] A high rate (20 percent) of hemopericardium was observed after atrial penetration. Because the atrial free wall is notably delicate and thin, the interatrial septum was selected as the safest location for electrode fixation. Bleeding that might occur at this site would be intracardiac, and small secondary septal fenestrations are known to be hemodynamically inconsequential.[3]

A no. 16 gauge Ross transseptal diagnostic catheterization needle[4] was modified to carry a T-shaped electrode tip and conducting wire across the septum (Fig. 1). The electrode was fabricated by connecting a multistrand

steel wire (Davis & Geck, 12569-60, Electrode) through a hole in the midsection of a 10 mm cylinder of 20 gauge steel tubing at a 90° angle by a cold press technique. For optimal contact, the Teflon® insulation was removed for a distance of 2 cm from the tip. A 7 mm slit was made down the inner curve of the needle and its protecting catheter to accommodate the conducting wire. A broad plastic stop-screw was created to clasp and stabilize the needle and catheter proximally, thus to prevent pre-emergence of the needle, should the catheter slide back, and of the electrode, should the catheter slide forward.

The atrial septum was approached through the right femoral vein and the fossa ovalis located beneath the limbic edge by fluoroscopy and palpation, as described by Bloomfield and Sinclair-Smith.[3] After septal puncture, an intraluminal probe served to eject the electrode tip into the left atrium. The electrode fixing apparatus was then removed and the electrode tip pulled snugly against the septum by gentle traction.

Results

Animal Experiments

Initial experiments indicated that to achieve safe electrode placement consistently it was necessary to increase the distal angle of the Ross needle from 15° to 35° and to select dogs weighing more than 45 kg. When the unmodified needle was used in small dogs, penetration of the roof of the right or left atrium usually occurred.

Ten dogs were observed for several months after electrode implantation to determine pacing thresholds and pathologic changes at autopsy. The proximal end of the electrode was coiled subcutaneously at the venous cut-down site between threshold tests. Average pacing thresholds increased from 3.5 ma initially to 7.2 ma several months after implantation (Table I). At autopsy, the electrode was firmly affixed in each animal and could not be removed manually. Various degrees of fibrosis on either side of the septum constituted the sole pathologic finding. On the left, the tip was partially or completely endothelialized in all animals (Fig. 2); on the right, a tuft of endothelium surrounded the electrode for a distance of 3 to 15 mm away from the septum (Fig. 3).

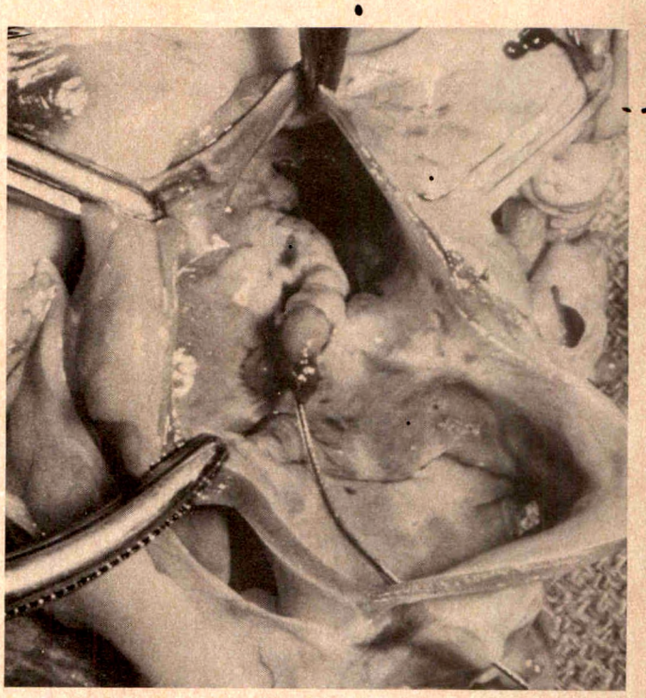

FIGURE 2 (left). The electrode tip endothelialized to the left atrial septum 3 months after implantation.
FIGURE 3 (right). The electrode endothelialized to the right atrial septum 12 months after implantation.

Clinical Case

A 78 year old man with carotid sinus syncope was evaluated for permanent pacing. Gentle carotid massage produced periods of asystole extending up to 9 seconds. Administration of atropine failed to block the hypersensitive reflex. Marked cardiomegaly, antecedent heart failure and normal A–V conduction prompted the conclusion that atrial rather than ventricular pacing would be most beneficial. In August 1972, after the animal experiments, a unipolar electrode was attached to the interatrial septum by way of the right femoral vein under local anesthesia and fluoroscopic guidance. A chest roentgenogram and gentle cardiac pulsations transmitted through the electrode confirmed its desired location and fixation. Electrocardiograms documented atrial capture at a pacing threshold of 2 ma and a pacemaker impulse–QRS interval of 180 msec (Fig. 4). The electrode was then attached to a Merc pulse generator which was implanted subcutaneously in the right lower abdomen. The patient has remained asymptomatic, and carotid massage no longer induces asystole. Serial electrocardiograms have shown a mixture of normal sinus rhythm at rates between 75 and 100 beats/min and artificial A–V pacing at 72 beats/min.

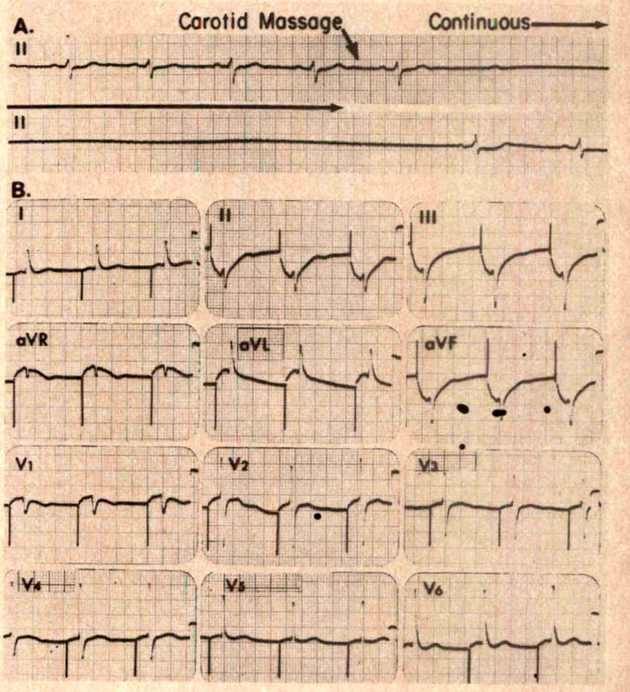

FIGURE 4. The electrocardiogram during and after carotid sinus massage **(A)** and atrial pacing **(B)** in clinical case.

Discussion

Synchronized A–V contraction should be preserved in the treatment of symptomatic bradyarrhythmias with an ideal pacemaker system.[5] Coordinated contractions can be achieved in patients with a "sick sinus" node syndrome and intact A–V conduction—including patients with carotid sinus syncope—by the use of a single electrode attached to the atrium. In patients with A–V block, pacing may be performed synchronously[6] with atrial sensing or sequentially[7] with atrial and ventricular stimulation, using a pair of electrodes.

Coordinated A–V pacing is not currently provided for most patients, in part because atrial pervenous electrodes lack stability and fail to maintain endocardial contact. Free-floating electrodes positioned at various locations inside the right atrium have proved uniformly unreliable for long-term pacing.[8] Three innovations designed to stabilize atrial electrodes have been reported with variable results.

Available techniques for permanent atrial pacing: The coronary vein offers a convenient narrow passageway leading off the atrium which may be cannulated for pacing. Successful, although inadvertent, pacing from this site was reported simultaneously by Moss et al.[9] in this country and Hunt and Sloman[10] in England in 1968. Subsequently, Kramer and Moss[11] achieved successful long-term results in 10 of 14 patients by electrode catheterization of the proximal portion of the great cardiac vein. Several complications have been reported that relate to the mobility of unattached electrodes, including high thresholds and early pacing failures,[12] electrode migration upstream to the left ventricle with loss of atrial pacing and distressing diaphragmatic stimulation,[13] and migration locally with venous perforation and cardiac tamponade.[14] Coronary sinus pacing has been inconsistent in my experience. In one patient, alternating atrial and ventricular pacing was observed in response to various positions assumed by the patient during the pacing trial. Finally, the coronary sinus is not cannulated easily in many patients. For these reasons, coronary venous catheterization has not gained wide acceptance for long-term atrial pacing.

Curved electrodes that impinge the atrial endocardium have been used,[15] and preformed J-shaped electrodes have been fabricated that may be lodged in the right atrial appendage.[16] A central stylet is used to straighten the J configuration before cardiac cannulation. Such electrodes can be manipulated easily into the appendiceal cavity where they have been used quite successfully for atrial pacing[16,17] and synchronous[18] and sequential[7] A–V pacing in 90 percent of 58 cases reported. Failures resulted from electrode disengagement. In contrast to electrodes placed in the ventricle, electrodes lodged in the atrial appendage do not become endothelialized in most instances. Endothelial fixation was not observed by Smyth et al.[17] at autopsy in any of their 15 dogs after several months of pacing, and electrode fixation to the atrial endocardium has been documented in only one human subject to date. Lacking firm endocardial fixation, this method falls short of the desideratum for flawless atrial sensing and pacing.

Finally, a group from East Germany has described a technique that involves an anchor-tipped electrode extruded into the right ventricle[19] or the atrial appendage,[20] designed to attach itself to the endocardium by one or both of its wings. Successful atrial pacing has been reported in 15 consecutive patients. This innovation approaches the objective of permanent atrial pacing; however, two shortcomings are apparent. First, the anchor-tipped electrode is not attached to a preselected site; fixation is dependent upon one of its wings being snagged on a trabeculation. Second, hemopericardium may result from electrode penetration of the atrial wall, a possibility not appreciated by the clinical observations of the European investigators. Results of animal experiments with the anchor-tipped electrode have not been reported.

Hazards of transseptal atrial pacing: Transseptal left atrial puncture is associated with significant risks; the greatest involves cardiac and aortic perforation with subsequent tamponade and, rarely, death, occurring at a frequency of 2, 1 and 0.3 percent, respectively, among 2,219 cases reported from here[21,22] and abroad.[23] Other hazards include femoral thrombophlebitis, pulmonary and systemic embolization, retroperitoneal hemorrhage and arrhythmias. Transseptal puncture is not a simple procedure. Unsuccessful results because of technical difficulties have been reported in 5 percent of 454 patients.[23] These difficulties and complications must be weighed against the morbidity, mortality and greater expense involved in a limited thoracotomy whereby epicardial electrodes may be sutured directly to the atrium.

A safety feature has been added to the Ross technique[4,22] in the method described here to minimize the risks of cardiac and aortic perforation. During preliminary experiments, pre-emergence of the needle and cardiac perforations occurred in several dogs when the operator attempted to secure the catheter proximally with one hand while manipulating the needle into position against the fossa ovalis with the other. These results led to the development of a stop-screw (Fig. 1) to stabilize the needle inside its protecting catheter until the moment of transseptal puncture. Subsequently, cardiac perforations were not observed.

Pacing thresholds: Elevated and variable pacing thresholds found in these experiments were unexpected (Table I). In 8 of 10 dogs thresholds increased with the passage of time; in the other two dogs, thresholds decreased. The highest thresholds were noted in dogs that had the most fibrosis around the electrode tip and conducting wire at autopsy. Thresholds exceeding 12 ma may be excessive for certain implantable pulse generators available today. Use of smaller electrode tips may result in lower thresholds and less fibrosis. The surface area of an electrode is directly related to the energy required for pacing.[8,24]

Clinical implication: The prevailing concept that permanent pervenous atrial pacing is unreliable because of electrode instability[8,16] need not be true. Consistent atrial pacing may be achieved by attaching pervenous electrodes to the interatrial septum. Further experimental and clinical experience is needed to establish the long-term reliability and safety of this new technique.

Evaluation of Patients with Pulmonary Atresia and Intact Ventricular Septum by Double Catheter Technique

ROBERT M. FREEDOM, MD
ROBERT I. WHITE, Jr., MD*
CHARLES S. HO, MD
ROBERT L. GINGELL, MD
RICHARD E. HAWKER, MB
RICHARD D. ROWE, MD

Baltimore, Maryland

Accurate definition of the site and length of the atretic segment in the patient with pulmonary atresia and intact ventricular septum is of prognostic and surgical significance. A double catheter technique was developed to allow precise localization of the site of atresia, whether valvular, infundibular, or both. Simultaneous opacification of the pulmonary artery by way of the ductus arteriosus or systemic to pulmonary arterial anastomosis by one catheter and the right ventricle by the second catheter was accomplished in five patients with pulmonary atresia, severe hypoplasia of the right ventricle and intact ventricular septum. The patients were 2 days to 17 months of age and weighed 3,200 to 9,200 g at the time the technique was applied. In these patients, the site of atresia proved to be valvular in one, and both valvular and infundibular in four. The double catheter technique is also applicable to patients with ventricular septal defect and acquired or congenital pulmonary atresia who have had palliative shunts, and to patients with complex transpositions and pulmonary atresia.

Although pulmonary atresia with an intact ventricular septum is an uncommon and serious type of cyanotic congenital heart disease, early recognition,[1–3] accurate diagnosis[4–6] and aggressive surgical therapy[7–14] have led to increased salvage of infants with this condition.

The size of the right ventricular cavity and site of atresia, whether valvular, infundibular, or both, have obvious important prognostic and surgical implications. Although several avenues of surgical therapy are currently in use,[7–14] a direct attack on the valve combined with a systemic to pulmonary arterial anastomosis has been advocated by some in those patients with pulmonary atresia and hypoplastic right ventricle.[11]

Although most reports suggest that the pulmonary atresia in patients with an intact ventricular septum is confined to the valvular level,[1,3,11,15,16] Morgan et al.[17] and other investigators[10,12–14] have documented both valvular and infundibular atresia. The observation of combined valvular atresia and either severe infundibular stenosis or atresia has also been common in our experience.

We recently studied five patients with pulmonary atresia and intact ventricular septum using a double catheter technique. The method allows simultaneous opacification of the pulmonary artery and the right ventricle and, hence, precise localization of the site and length of obstruction. In this communication we present this technique and our preliminary results with a discussion of other possible applications.

Patient Selection and Methods

Five patients with pulmonary atresia and intact ventricular septum were studied. All had severe hypoplasia of the right ventricle. The double catheter

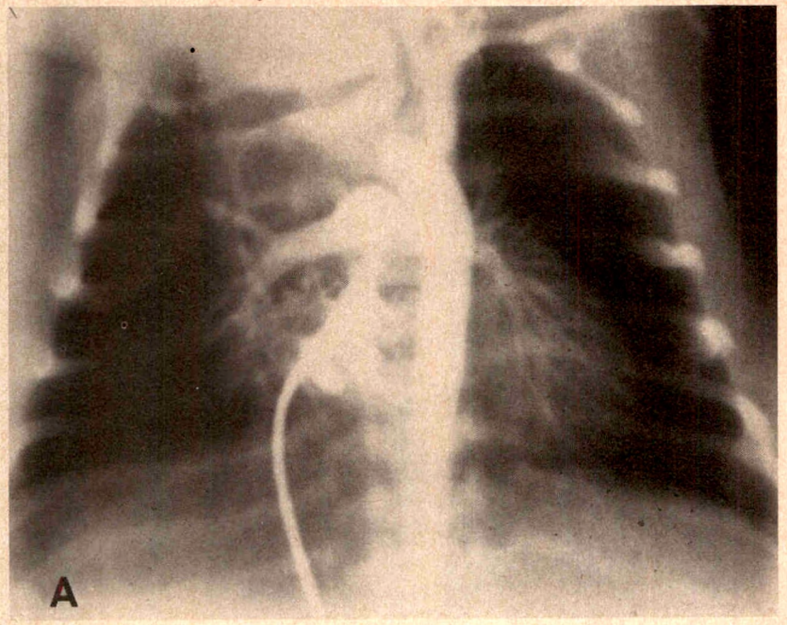

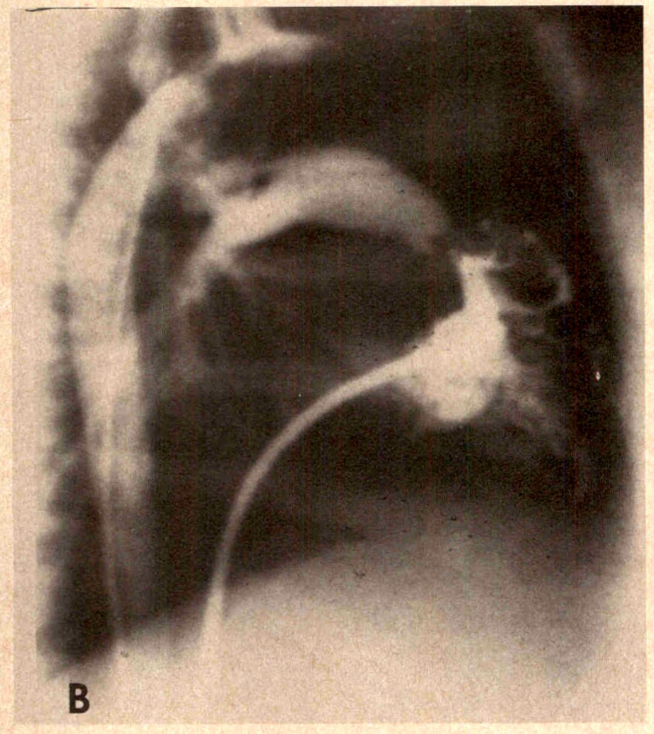

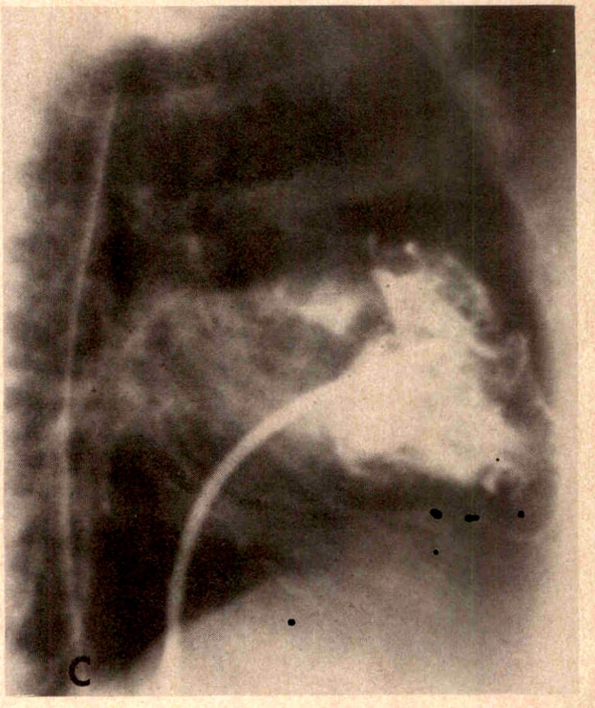

FIGURE 1. A and **B,** simultaneous biplane right ventriculogram and thoracic aortogram in a 2 day old infant weighing 3.2 kg. **C,** later radiograph from the same angiogram in the lateral projection. The early radiographs **(A, B)** demonstrate a small, heavily trabeculated right ventricular chamber with opacification of myocardial sinusoids **(B).** The pulmonary artery is of normal caliber, and retrograde visualization to the level of the atretic valve is noted. The atresia seems primarily valvular, but the distal infundibulum is severely stenotic. As shown in **C,** it is difficult to estimate the length of the atretic segment from a standard right ventricular angiogram.

technique was applied to one newborn infant before performance of a systemic to pulmonary arterial anastomosis, and in the other four patients after the shunt procedures. The patients were aged 2 days and 4, 5 1/2, 6 and 17 months and weighed 3.2, 4.8, 5.3, 4.3 and 9.2 kg, respectively.

At cardiac catheterization, an angiographic catheter was advanced to the right ventricle by the saphenous, femoral or axillary venous approach. In the 2 day old infant, a modified umbilical arterial catheter[18] was advanced through the umbilical artery to the level of the patent ductus arteriosus. In the infant who had previously undergone an ascending aorta to right pulmonary arterial anastomosis, the arterial catheter was positioned in the ascending aorta by way of the right axillary artery. Three patients had undergone a descending thoracic aorta to left pulmonary arterial anastomosis (Potts' shunt). In these patients, the arterial catheter was introduced into the femoral artery and advanced into the pulmonary artery by way of the Potts' communication. Opacification of the right ventricle and pulmo-

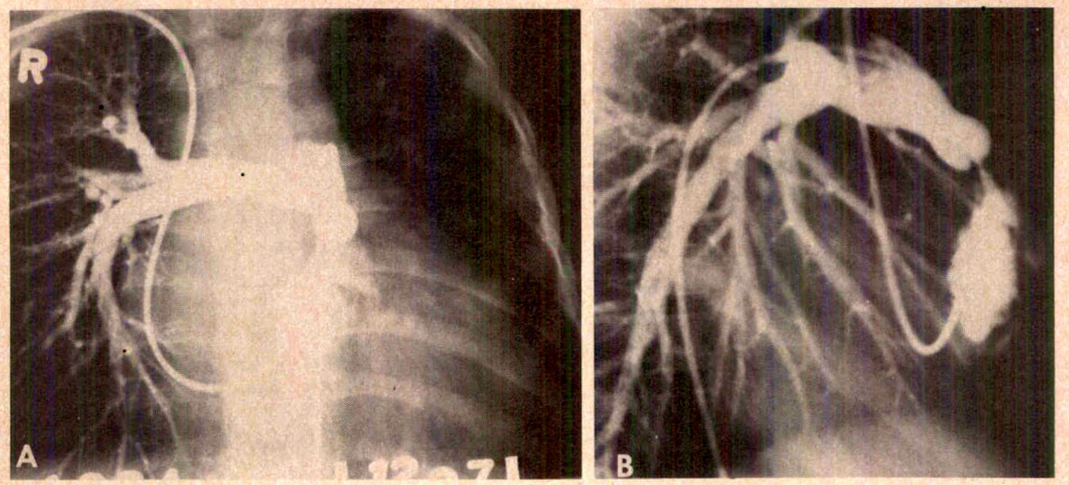

FIGURE 2. A and **B,** simultaneous right ventriculogram and retrograde pulmonary arteriograms (selective catheterization of Potts' anastomosis) in a 17 month old child weighing 9.2 kg. A small right ventricular cavity with a hypoplastic, severely narrowed infundibulum is demonstrated. Excellent opacification of the main and right pulmonary artery is obtained. The left pulmonary artery is not opacified because of rapid washout of blood from the Potts' anastomosis. The pulmonary valvular annulus is minimally narrowed and pulmonary valvular tissue is identified despite atresia. A right ventricular angiogram performed immediately before the double catheterization demonstrated pulmonary atresia but did not define the length or site of the atretic segment.

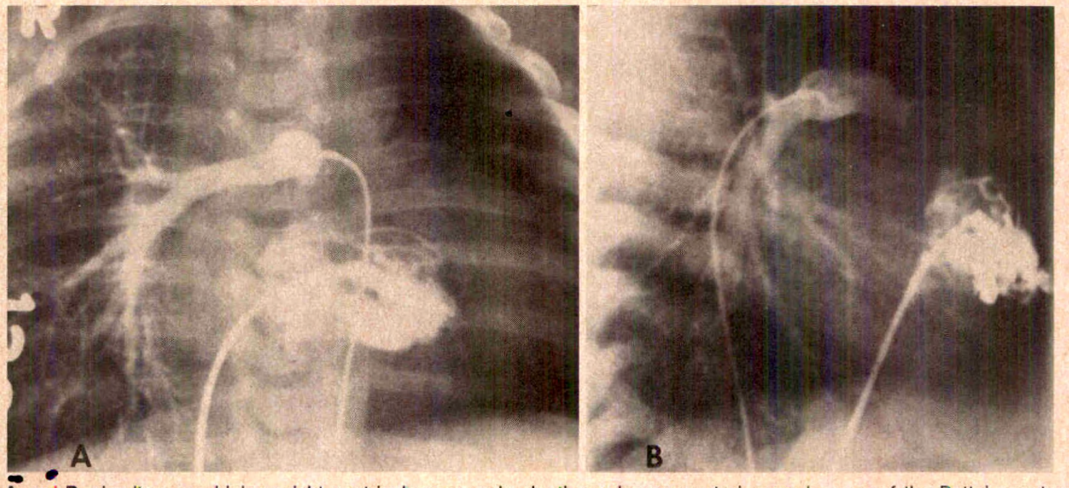

FIGURE 3. A and **B,** simultaneous biplane right ventriculogram and selective pulmonary arteriogram by way of the Potts' anastomosis in a 4 month old infant who weighed 4.8 kg. In contrast to the findings in Figures 1 and 2, a long atretic segment is demonstrated between the pulmonary valve and right ventricle. A simple valvotomy in this patient probably would not be effective.

nary artery was obtained by hand injection of 0.25 to 0.50 ml/kg body weight of contrast material into the right ventricle and simultaneous pressure injection of 1.00 to 1.25 ml/kg of contrast material through the arterial catheter into the pulmonary artery. Serial biplane radiographs were then obtained in the anteroposterior and lateral projections at filming rates of 6 or 12 films/sec for the first 2 seconds.

Results

Successful simultaneous opacification of the diminutive right ventricle and pulmonary artery was accomplished in all five patients. Catheterization of the pulmonary artery from the right ventricle was not possible because of the congenital pulmonary atresia. However, direct catheterization of the pulmonary artery by way of the Potts' communication was performed in three patients.

This technique allowed precise definition of the site and extent of the congenital pulmonary atresia. All of the patients in this study had type I pulmonary atresia with a small or tiny right ventricle.[3] In one patient, the atresia was localized to the valve, but the infundibulum of this patient was severely hypoplastic and narrowed (Fig. 1). In the other four patients, the atretic segment appeared to be both valvular and infundibular, and of considerable length (Fig. 2 and 3). In addition, the proximal main pulmonary artery was absent in one case. Abnormal intramyocardial sinusoid-coronary arterial communications were

demonstrated in all five patients.[19] All five had a hypertensive right ventricle by standard pressure recording.

Discussion

The double catheter technique allows definition of the site and extent of the pulmonary atresia, and in this small series, the method produced no complications. The umbilical artery provides easy access to the descending thoracic aorta in neonates and has been used for some time in catheterization procedures in infants.[20] In older infants, the technique requires cannulation of a peripheral artery. We have recently been using the new system described by White et al.[21] for percutaneous arterial catheterization in the small infant.

Although in many patients with pulmonary atresia and intact ventricular septum, the atretic segment is localized to the valve, our results and the observations of others suggest that this finding is not invariable. A valvotomy alone without infundibulectomy would probably be ineffectual in the patient with both valvular and infundibular atresia, or severe infundibular narrowing. Yet a successful valvotomy in a patient with type I pulmonary atresia and isolated membranous valvular atresia may be beneficial by providing an opportunity for more volume change at less systolic pressure.[11] Furthermore, decompression of the hypertensive right ventricle might lead to diminution of the abnormal intramyocardial sinusoid-coronary arterial communications and their deleterious effects.

Although acquired infundibular atresia has been documented by serial angiocardiography in patients with tetralogy of Fallot,[22,23] this has not been demonstrated in patients with pulmonary valvular atresia and intact ventricular septum. In our four older infants comparison of findings obtained by the double catheter technique with those obtained by standard right ventricular angiography (performed in the neonatal period) showed no substantial changes in the appearance of the right ventricle, thus suggesting that the infundibular atresia was not acquired.

The double catheter technique is also applicable to the study of tetralogy of Fallot and pulmonary atresia, either acquired or congenital, and to complex transpositions with associated pulmonary atresia,[24,25] as well as pulmonary atresia with intact ventricular septum. Accurate definition of the type of pulmonary atresia by this technique may lead to improved surgical results in these difficult cases.

Echocardiographic Assessment of Cardiac Malposition

RICHARD A. MEYER, MD
DAVID C. SCHWARTZ, MD, FACC
WESLEY COVITZ, MD
SAMUEL KAPLAN, MD, FACC

Cincinnati, Ohio

Isolated dextrocardia or isolated levocardia almost invariably indicates the presence of a complex cardiac anomaly. An accurate anatomic diagnosis in patients with these malformations requires knowledge of the atrial position, the relative position of the ventricles (atrioventricular concordancy or discordancy) and the presence or absence of a ventricular septum. Fifteen patients were studied to demonstrate that diagnostic ultrasound, in conjunction with the plain chest roentgenogram, provides a noninvasive method for accurately assessing atrioventricular relations and arrangement of the great vessels, in the presence of isolated discordancy of the cardiac apex. The patients studied were aged 10 months to 17 years; seven had isolated dextrocardia, five had situs inversus totalis, two had isolated levocardia and one had levocardia with abdominal heterotaxy. Thirteen of the 15 patients evaluated by echocardiography underwent cardiac catheterization and angiography. The correct diagnosis was made from the echograms and plain chest roentgenograms alone in 11 of the 13 patients. We conclude that with echocardiography and the knowledge of atrial situs, it is possible to define accurately important anatomic relations before cardiac catheterization in patients with cardiac malposition.

Isolated discordancy of the cardiac apex, whether in situs solitus or situs inversus, almost invariably indicates the presence of a complex cardiac anomaly.[1] Ventricular inversion (levotransposition of the great vessels), single ventricle and atrioventricular valve anomalies are among the most frequent anomalies encountered.[2] An accurate anatomic diagnosis in patients with these lesions requires knowledge of the atrial position, the relative position of the ventricles and the presence or absence of the interventricular septum as well as the arrangement of the great vessels.

The anatomic diagnosis of cardiac defects in patients with cardiac malposition is difficult and depends upon cardiac catheterization and selective angiocardiography. Atrial and abdominal situs may be determined from the tracheobronchial air column on a plain chest roentgenogram.[3] Discordance of the atrial situs with the abdominal viscera rarely occurs.[4] The use of echocardiography in the evaluation of heart disease in adults has been well established[5] and has been successfully applied in many congenital cardiac defects.[6,7]

It is the purpose of this paper to demonstrate that diagnostic ultrasound, in conjunction with the plain chest roentgenogram, can provide a noninvasive method for accurately assessing atrioventricular relations, the presence or absence of a ventricular septum and arrangement of the great vessels in the presence of isolated discordancy of the cardiac apex.

Material and Methods

Case material: Fifteen patients between the ages of 10 months and 17 years were studied by ultrasound; 13 also underwent cardiac catheterization

TABLE I

Summary of Data in 15 Patients with Cardiac Malposition

Case no.	Age (yr)	Plain Chest Roentgenogram	Echographic Diagnosis	Cineangiographic Diagnosis
1	1 6/12	Dextrocardia, situs solitus	Tetralogy complex	Truncus arteriosus (type II), situs solitus
2	2	Dextrocardia, situs solitus	L-TGV	L-TGV, VSD, PS, situs solitus
3	3 10/12	Dextrocardia, situs inversus	D-TGV	D-TGV, VSD, PS, situs inversus
4	8	Dextrocardia, situs solitus	?	TOF, superiorly displaced LV, situs solitus
5	6 7/12	Dextrocardia, situs inversus	A–V concordance, normally related great arteries	Mirror-image dextrocardia, ASD, VSD
6	7	Dextrocardia, situs inversus	A–V concordance, normally related great arteries	Mirror-image dextrocardia, VSD, PS
7	1 2/12	Dextrocardia, situs solitus	L-TGV	L-TGV, VSD, situs solitus
8	17	Dextrocardia, situs solitus	A–V concordance, normally related great arteries	...
9	11	Dextrocardia, situs inversus	A–V concordance, normally related great arteries	...
10	6 6/12	Dextrocardia, situs inversus	L-TGV	L-TGV, VSD, PS, situs inversus
11	7 8/12	Levocardia, situs inversus	A–V concordance, normally related great arteries	VSD, PS, abdominal situs inversus
12	11 4/12	Levocardia, situs inversus	A–V concordance, normally related great arteries	ASD, VSD, PH, abdominal situs inversus
13	9 8/12	Dextrocardia, situs solitus	L-TGV	L-TGV, situs solitus
14	7 6/12	Levocardia, abdominal heterotaxy	Single ventricle, D-TGV	Single atrium & ventricle, D-TGV, situs ambiguous
15	1 1/12	Dextrocardia, situs solitus	Single ventricle, L-TGV	Single ventricle, L-TGV, situs solitus

ASD = secundum atrial septal defect; A–V = atrioventricular; D-TGV = dextrotransposition of the great vessels; L-TGV = levotransposition of the great vessels; LV = left ventricle; PH = pulmonary hypertension; PS = pulmonic stenosis; RV = right ventricle; TOF = tetralogy of Fallot; VSD = ventricular septal defect.

(see Table I). Seven patients had isolated dextrocardia, five had situs inversus totalis, two had isolated levocardia and one had levocardia with abdominal heterotaxy. The cardiac lesions in the patients with dextrocardia consisted of levotransposition of the great vessels, single ventricle, truncus arteriosus (type II) and one instance of ventricular septal defect with an atrial septal defect. In the latter case, the left ventricle was superior, leftward and anterior to the right ventricle. Of the five patients with situs inversus, two had dextrotransposition of the great vessels, one had a ventricular septal defect with pulmonic stenosis, one had a ventricular septal defect with an atrial septal defect in addition to sequestration of the right lower pulmonary lobe, and one patient had a normal heart. One patient with isolated levocardia had a single ventricle, and the other had a normal heart. The patient with abdominal heterotaxy and levocardia was thought to have a single ventricle with dextrotransposition.

Echocardiographic technique: With patients in a supine position, ultrasound examinations were performed using a Hoffrel Ultrasonoscope (model 101 with model 704 slow sweep accessory). In children less than 1 year of age, a 3.5 or 5.0 megahertz nonfocused transducer with an outer diameter of 0.25 inch was used. In older patients a 2.25 megahertz, 0.25 or 0.50 inch transducer focused at 5 cm was used. A water-soluble gel was utilized to insure an airless contact between the patient's skin and the transducer.

Plain chest roentgenograms were obtained in all patients to determine the position of the cardiac apex and visceral situs. When the apex was to the left, the ultrasound examination began to the left of the sternal border. If the apex was to the right, the examination was begun to the right of the sternal border. Echocardiographic relations assume significance only when the position of the transducer as well as the path of the ultrasound beam are known. These relations are stated in terms of left or right, superior or inferior and anterior or posterior. The sequence of structures examined was as follows: (1) the mitral valve, identified by its continuity with a semilunar valve, (2) the great vessel in continuity with the mitral valve, (3) the tricuspid valve, (4) the second root structure, and (5) the interventricular septum. The positions of the structures present were carefully noted and indicated on a line drawing of the heart and chest cavity. After analysis of the echograms and roentgenograms, a descriptive anatomic diagnosis of the cardiac defect was made. The cineangiogram of each patient was then reviewed and the angiographic diagnosis was compared with the echographic diagnosis.

Results

Tracheobronchial tree and visceral situs: Atrial and visceral situs were determined from the roentgenograms as described by van Mierop et al.[3] Figure 1A is an example of a normal tracheobronchial tree

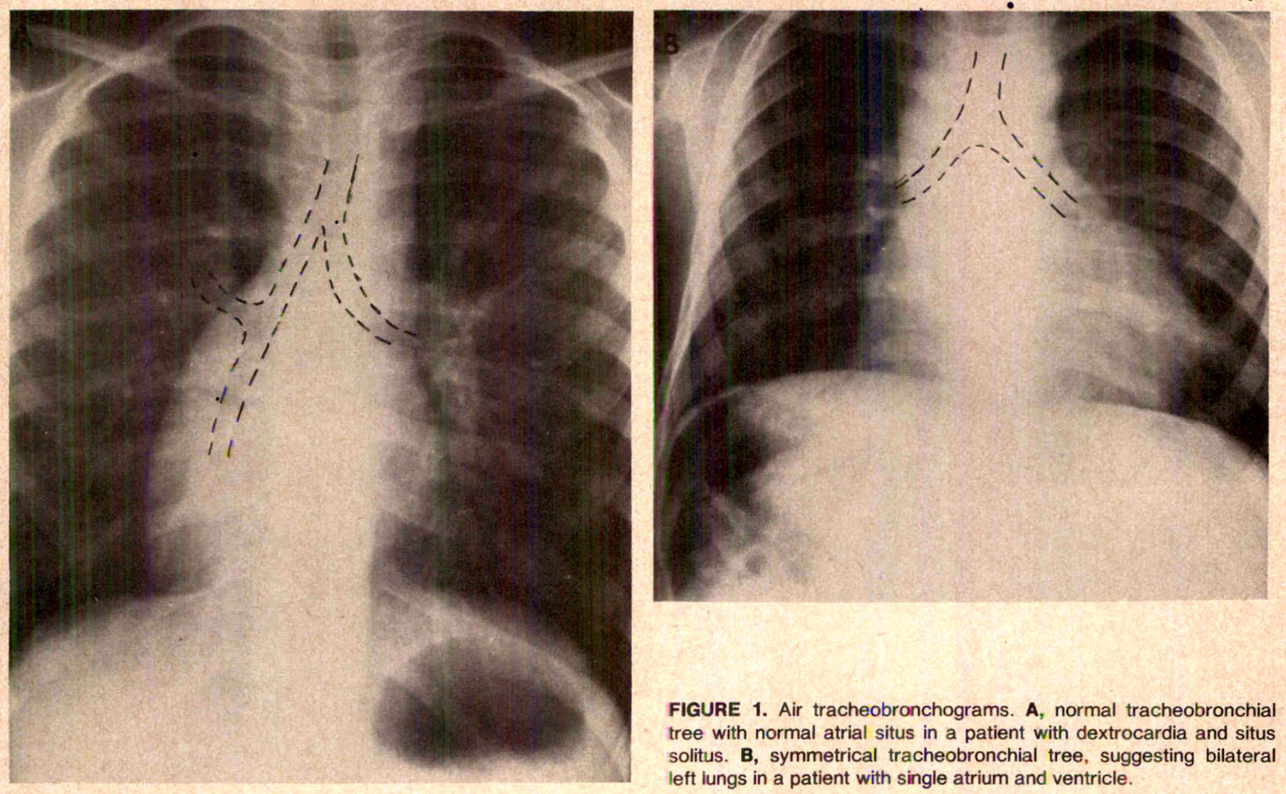

FIGURE 1. Air tracheobronchograms. **A,** normal tracheobronchial tree with normal atrial situs in a patient with dextrocardia and situs solitus. **B,** symmetrical tracheobronchial tree, suggesting bilateral left lungs in a patient with single atrium and ventricle.

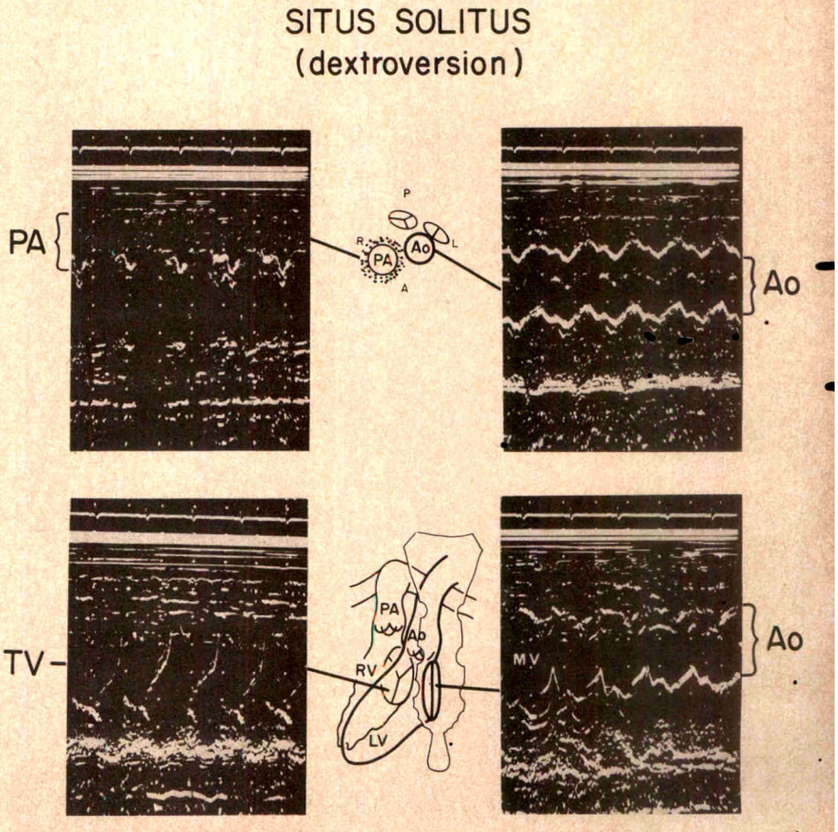

FIGURE 4. Case 8. Composite picture demonstrating the anatomic-echographic relations of the cardiac structures in a patient with isolated dextrocardia and normally related structures. Abbreviations as in Figure 2.

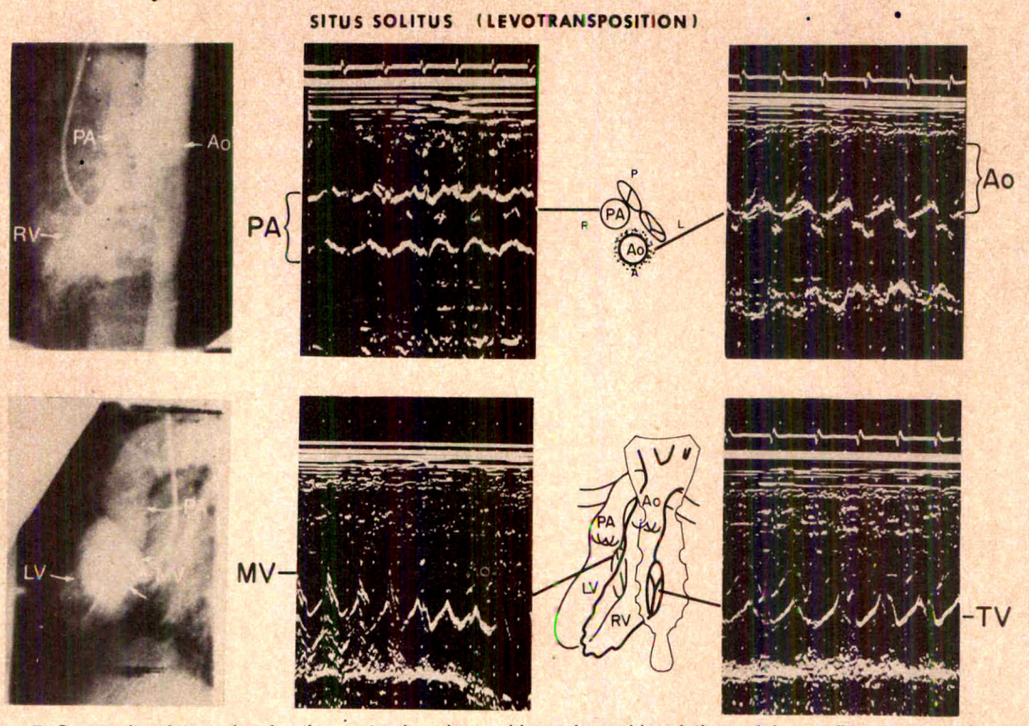

FIGURE 5. Case 7. Composite picture showing the anatomic-echographic-angiographic relations of the cardiac structures in a patient with isolated dextrocardia and ventricular inversion. The aortic root echo was obtained anteriorly and to the left. Abbreviations as in Figure 2.

and gastric air shadow in a patient with a normal atrial and visceral situs (solitus) and dextrocardia with levotransposition of the great vessels. The symmetrical appearance of the tracheobronchial tree of the patient shown in Figure 1B suggested bilateral left lungs, a lesion frequently associated with polysplenia and complex intracardiac anatomy.[10] This patient had a single ventricle with a common atrium.

Normal heart: Figure 2, obtained from a patient with normal situs and a normal heart, shows the sternal landmarks and transducer position in relation to the underlying structures. The echo of the anterior leaflet of the mitral valve was recorded posteriorly and to the left of the tricuspid valve and was in continuity with the aortic root. The pulmonary root was recorded anteriorly and to the left of the aortic root. Since the pulmonary root arose from an infundibulum, it was not continuous with an atrioventricular valve. Thus, the cardiac relations in this patient were normal.

Mirror-image dextrocardia: Figure 3 is from Patient 5, who had dextrocardia and visceral situs inversus (total situs inversus). As expected, the mitral valve echo was obtained to the right of and posterior to the tricuspid valve. The anterior root echo was recorded to the right of the posterior root echo. These findings suggested mirror-image dextrocardia. Clinically, the patient had a normal heart.

Isolated dextrocardia with normally related great vessels: Figure 4 is from Patient 8, who had isolated dextrocardia. From the right sternal border, the mitral valve echo was recorded to the left of and anterior to the tricuspid valve. The pulmonary arterial echo was obtained anteriorly and to the right of the aorta. These echographic findings, in conjunction with the plain chest roentgenogram, suggested that there was atrioventricular concordance with normally related great vessels, that is, dextroversion of the heart.

Isolated dextrocardia with levotransposition of great vessels: Figure 5 demonstrates the findings in Patient 7, who had isolated dextrocardia. In this patient, the mitral valve echo was recorded posteriorly and to the right of the tricuspid valve. The great vessel echo, in continuity with the atrioventricular valve, was obtained posteriorly and to the right, whereas the anterior great vessel was recorded to the left. These echographic findings, together with the plain roentgenogram, suggested atrioventricular discordancy with transposed great vessels in a patient with situs solitus. The angiograms confirmed the diagnosis of levotransposition of the great vessels. The aorta arose from a morphologic right ventricle and to the left of the pulmonary artery. The left ventricle gave rise to a pulmonary artery, which was in continuity with the mitral valve.

Situs inversus totalis with dextrotransposition: Figure 6 illustrates the findings in Patient 3, who had situs inversus totalis. The mitral valve echo was recorded to the right of the tricuspid valve. The great vessel, in continuity with the mitral valve, was recorded posteriorly and slightly to the right, whereas the anterior root echo was recorded to the left. These findings were compatible with the diagnosis of dextrotransposition of the great vessels in a patient with situs inversus.

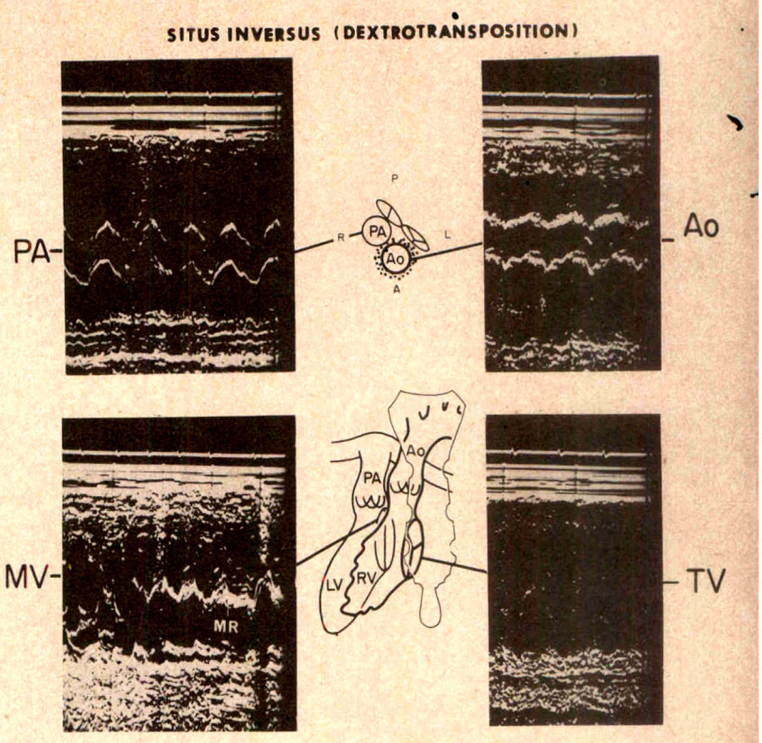

FIGURE 6. Case 3. This composite shows the anatomic-echographic relations of the cardiac structures in a patient with situs inversus and dextrotransposition. The left ventricle is on the right, but the anterior root echo was recorded to the left. MR = mitral ring; other abbreviations as in Figure 2.

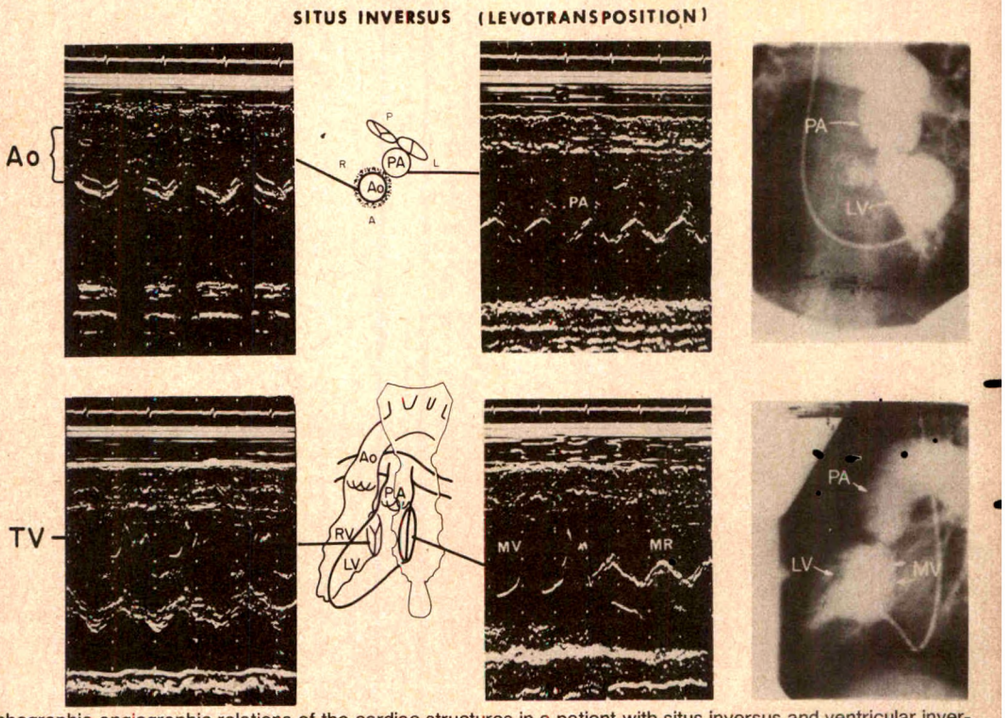

FIGURE 7. Case 10. Anatomic-echographic-angiographic relations of the cardiac structures in a patient with situs inversus and ventricular inversion. The anterior root echo was to the right, which suggested transposed great vessels. Angiography confirmed the diagnosis. Abbreviations as in Figures 2 and 6.

Situs inversus totalis and ventricular inversion: Figure 7 shows the findings of Patient 10, who had situs inversus totalis and ventricular inversion (levotransposition of the great vessels). The mitral valve echo was recorded to the left of the tricuspid valve and the anterior root echo was obtained to the right of the posterior root echo. These findings suggested levotransposition of the great vessels in a patient with situs inversus, and this diagnosis was confirmed by selective angiography.

Single ventricle: Figure 8 is from Patient 14, who had bilateral left lungs and situs inversus abdomi-

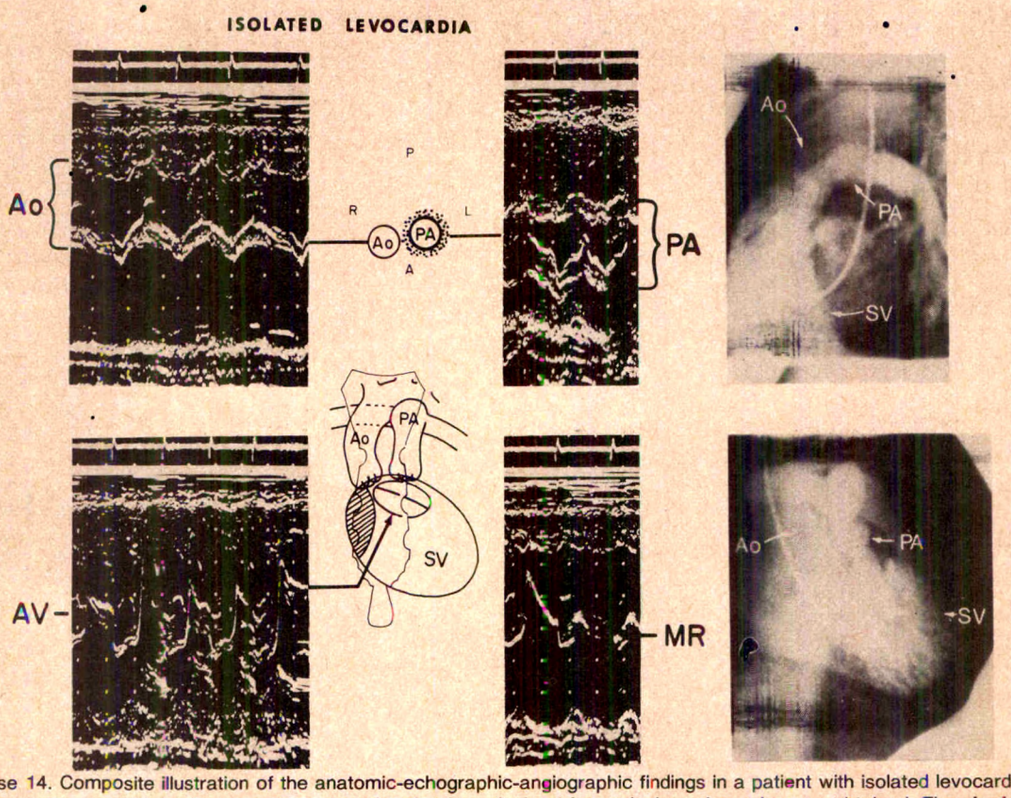

FIGURE 8. Case 14. Composite illustration of the anatomic-echographic-angiographic findings in a patient with isolated levocardia and indeterminate situs. A ventricular septal echo was not recorded and only a single atrioventricular valve echo was obtained. The **shaded area** represents the noninverted infundibulum. The anterior root echo was found to the right. Angiography confirmed the diagnosis of single ventricle and single atrium. A = anterior; Ao = aorta; AV = atrioventricular valve; L = left; MR = mitral ring; P = posterior; PA = pulmonary artery; R = right; SV = single ventricle.

nalis. A ventricular septal echo was not obtained and only a single atrioventricular valve echo was recorded. In addition, the anterior root was recorded to the right of the posterior root. These findings suggested single ventricle with dextrotransposition of the great vessels, and this diagnosis was confirmed by angiography.

Thirteen of the 15 patients studied by ultrasound underwent cardiac catheterization and angiography. The correct diagnosis was made from the echograms and plain chest roentgenograms alone in 11 of the 13 patients.

Discussion

Identification of the position of the left ventricle in patients with complex cardiac malformations is essential to correct diagnosis. This can be accomplished with the use of echocardiography because of the following anatomic features: (1) The atrioventricular valve follows the distal ventricular chamber,[8] and (2) with rare exception, the anterior leaflet of the mitral valve is in fibrous continuity with the semilunar valve arising from the morphologic left ventricle.[9] Thus, the characteristic echographic feature of the morphologic left ventricle is that its atrioventricular valve echo (mitral valve) is in continuity with a semilunar valve echo, whereas the tricuspid valve echo of the right ventricle is not in continuity with a semilunar valve echo.

Since ultrasound can determine the position of the left ventricle, the diagnosis of ventricular inversion can be made in patients with cardiac malposition. For example, in patients with isolated dextrocardia (situs solitus), the left ventricle should be recorded to the left (Fig. 4) unless there is ventricular inversion (Fig. 5). The converse is true in patients with total situs inversus. The left ventricle should be located on the right (Fig. 3) except in the presence of ventricular inversion (Fig. 7).

The arrangement of the great vessels can also be predicted by ultrasound. Although in our experience ultrasound cannot differentiate the aorta from the pulmonary artery, that information can be deduced if the relations of the root echoes and ventricles are known. For example, if a patient has situs inversus totalis (mirror-image dextrocardia) and the left ventricle is recorded to the right, then the expected position of the pulmonary artery is anterior and to the right (Fig. 3). However, if the anterior root echo is recorded either directly anterior to or to the left of the posterior root echo, then the great vessels are transposed and the anterior root is the aorta (Fig. 6).

Likewise, in a patient with isolated dextrocardia (visceral situs solitus) and a normally related heart,

the expected position of the pulmonary artery would be anterior and to the right (Fig. 4). However, if the left ventricle is to the right, implying ventricular inversion, then the anterior root is an aorta and the echo should be obtained to the left of the posterior root echo (Fig. 5).

Single ventricle can usually be detected by the absence of the ventricular septal echo and the presence of a single atrioventricular valve echo, which is in continuity with the posterior margin of the posterior root. In addition, the anterior margin of the posterior root echo may be difficult to record from the "mitral" valve position.

We conclude that with echocardiography and the knowledge of atrial situs, it is possible to define accurately important anatomic relations in a high percentage of patients with cardiac malposition. When catheterization is necessary, prior knowledge of the anatomic relations provided by diagnostic ultrasound will aid significantly in planning the study.

Experimental Mitral Insufficiency (Bettelheim and Kauders)

SAUL JARCHO, MD

New York, New York

During the last 8 years the historical series in this Journal has included occasional articles on the experimental physiology of the heart valves.[1–5] The present contribution continues this line of interest and is devoted to the work of Karl Bettelheim and Felix Kauders entitled "*Experimentelle Untersuchungen über die kunstlich erzeugte Mitral-Insuffizienz und ihren Einfluss auf Kreislauf und Lunge*" (Experimental researches on artificially produced mitral insufficiency and its effect on the circulation and the lungs). The original essay was published in *Klinische und Experimentelle Studien aus dem Laboratorium von Professor Basch*, Berlin, 1891–96, Volume 1, pages 144–170.

Although the experiments of Bettelheim and Kauders were undertaken in order to explain clinical phenomena, and some experiments by their predecessors were performed for both clinical and physiologic purposes, the entire experimental series can be made to serve incidentally as a historical introduction to surgery of the heart valves.

Excerpts from Paper by Bettelheim and Kauders

In the present work it has been our endeavor to study by experimentation in animals the disturbances that are produced by deficiencies in valves and in this manner to gain more exact insight into them. By this method a stronger basis for clinical deduction can be created.

In general our predecessors in this field went to work in such a way as to produce insufficiency artificially, i.e. by instrumental damage. Since our work had to do with mitral insufficiency only, we shall mention from the pertinent literature only that which refers to this defect of valves . . . [The authors summarize the work of Klebs,* Rosenbach† and Francois-Franck‡.]

These experiments gave information only about the change which the arterial pressure, i.e., the work of the left ventricle, undergoes in consequence of artificially produced valvular defects, since only the carotid pressure was measured.

These measurements alone are the basis for the inferences which have been drawn from these experiments concerning the behavior of the right ventricle. The simultaneous behavior of both ventricles during artificial mitral insufficiency was tested for the first time by Stricker*; in an investigation on this subject he measured the pressure in the pulmonary artery at the same time as the pressure in the carotid . . . .

After all the experimental information that exists on mitral insufficiency, it cannot be said that our understanding of this circulatory disturbance can be regarded as closed. It rests in part on experiments which must be considered incomplete, since they afford information about arterial pressure only, and in part on experiments which are complete, since they consider the pressure in the pulmonary artery along with the behavior of the arterial pressure but contradict present clinical opinion. This contradiction expresses itself in the fact that in Stricker's experiments the elevation of pressure in the pulmonary artery—which clinical observation must infer from the demonstrable hypertrophy of the right heart and from the accentuation of the second pulmonic arterial sound—is lacking. In this connection it must be noted that Stricker himself in his experiment does not go against current clinical opinion. On the contrary, he mentions an experimental finding in favor of it. In a dog affected by organic mitral insufficiency a strikingly high pressure was observed in the pulmonary artery.

An investigation which has as its purpose to study the working of mitral insufficiency must concern itself above all with repeating Stricker's experiments concerning simultaneous measurement of arterial and pulmonary pressures in established mitral insufficiency. Such repetition seemed indicated not only with respect to the behavior of the pressure in the pulmonary arteries but also with respect to the [peripheral] arterial pressure. With respect to the latter also, the results, as we have already indicated, appear to be not unequivocal.

As has been stated, we attributed special importance to the measurement of the pressure in the pulmonary artery. For this reason we must deal first with trials in which half of the thorax was opened. However, once the thorax has been opened, and the heart—especially the left atrium—has become accessible, it appears more suitable to employ Stricker's method for the production of mitral insufficiency rather than the methods used previously by Klebs, Rosenbach and others. When the valve is torn or cut, the experiment is abandoned totally to chance. As we have convinced ourselves on a previous occasion, this alone determines

whether a large or a small defect is made in the valve. The size of the defect cannot be known during the experiment itself but can only be ascertained at autopsy. Moreover, by this method under the same conditions only one experiment can be undertaken in one animal. Through more extensive procedures in the same experiment it is always possible to make larger lesions in the valve but obviously this is not a repetition of an experiment under the same conditions. Further, by the procedure of injuring the valve a condition is introduced during the experiment which can by no means be regarded as to some extent constant. Therefore when experiments are conducted by this method, the results are very difficult to evaluate since the requirement of constancy of basic conditions is not met.

Up to a certain point this requirement is much more easily met when mitral insufficiency is produced by Stricker's method. The valves remain uninjured and the character of the communication between ventricle and atrium is conditioned only by the width of the cannula and the size of the window in it. Hence, when one and the same cannula is introduced through the ventricle into the atrium in different animals, approximately the same insufficiency is created. We say approximately the same, because complete equivalence could be produced only if one were able to use animals of the same size which had hearts of the same size.

The method mentioned has the additional advantage that several trials can be made in one and the same animal. For this purpose it is merely necessary to equip the cannula with an obturator. As long as this is in the cannula and obstructs the window, there is no insufficiency. When the obturator is pulled out and the window is left unobstructed, insufficiency is produced. That the degree of insufficiency is always the same needs no further proof. It might be possible for the window in the cannula to become blocked by blood clots during the experiment. In our experiments this did not happen, as we convinced ourselves afterward. It must be mentioned that this method produces not pure insufficiency but insufficiency combined with stenosis, since the cannula encroaches upon the space in the ostium.

In the experiment we went to work as follows. The animal was tied down, curarized and given artificial respiration. After preliminary preparation of the right carotid artery for subsequent attachment of a mercury manometer, the left chest was opened by resection of three or four ribs. A branch of the pulmonary artery was prepared. Both this and the carotid were equipped with a rounded cannula and connected to a mercury manometer. In order to determine the normal pressure relations, for a short time, a double kymographic tracing was made from the carotid and the pulmonary branch. Then the pericardium was opened. The left auricle was drawn forward and a sling of thread was placed around it. The auricle was then opened with a scissors. By way of the hole the von Basch cannula mentioned by Stricker and equipped with an obturator was thrust through the atrium into the ventricle. The sling was then drawn together and the part of the cannula that protruded from the auricle was fixed in place. After these preparations the recording of both pressures was resumed and was continued throughout the entire duration of the experiment . . . .

As might be expected, the resistance to drainage of the blood from the lung is greater when the obturator is removed and continuous communication is established between the left atrium and ventricle. This creates a condition which is equivalent to that caused by insufficiency of the mitral valve. In agreement with this supposition our experiments show that the ratio between arterial pressure and pressure in the pulmonary artery actually becomes still smaller than it is in the presence of stenosis . . . .

The establishment of an uninterrupted communication between the left ventricle and the left atrium, i.e., a communication that is not interrupted by systolic closure of the mitral valve—in other words, the artificial creation of mitral insufficiency—reduces the arterial pressure and raises the pressure in the left atrium and that in the pulmonary artery.*

This result of our experiments agrees completely with the concepts that we had formed with respect to circulatory occurrences in mitral insufficiency. However, our experiments warrant a more exact examination of the conditions that prevail during continued mitral insufficiency, since not general concepts and presuppositions but direct measurements—not merely of the arterial pressure but also of the pressure in the left atrium and pulmonary artery—provide the basis for our understanding . . . .

Table IV [not reproduced in the present excerpts] includes all those cases in which both the arterial pressure and the pressure in the pulmonary artery rise during the insufficiency. In this table it can be seen that, except in the case marked with an asterisk, the arterial pressure rose more. This relatively greater rise in the arterial pressure indicates a relative increase in the numerator compared with the denominator in our experiments on the circulation and justifies the opinion that the conditions for compensation, in the clinical sense, are to be sought not in the right heart but in the left . . . .

As can be seen, the results of our experiments are not favorable to the dominant opinion, namely that compensation in mitral stenosis depends on additional work of the right heart. Our results, on the contrary, support the opinion that conditions such as exist in the left heart—or, to express the matter in a more general way—conditions which arise in the greater circulation, can exert a favorable influence on the circulatory impairment which develops during mitral insufficiency.

Further experiments will be necessary in order to clarify the nature of these conditions . . . .

With respect to the theory of compensation and its impairment our experiments furnish the dictum that compensation can occur not only in the presence of high arterial pressure but also in the presence of low arterial pressure and that a fall in arterial pressure is not always equivalent to impairment of compensation.

Starting with the figures in our experiments we have defined the concepts of compensation and of impaired compensation in a manner differing from what is customary among clinicians. For us compensation is equivalent to an increase in the proportional figure and impaired compensation is a decrease in the proportion; despite this, what we understand by compensation does not differ in principle from that which the term commonly signifies. The clinician infers compensation when symptoms are lacking which indicates profound circulatory impairment, e.g., dyspnea, dropsy, edema, phenomena of stasis, etc. Compensation in our sense is not recognizable by the lack of symptoms, i.e., negatively, but positively through the demonstration of a larger proportional figure, which corresponds to more favorable circulatory conditions. Thus it can be seen that in the final result our concept of compensation coincides with

* As already stated, the elevation of the pressure in the pulmonary artery is expressed clinically, according to a general assumption, by accentuation of the second pulmonic heart sound. Since the elevation causes increased work by the right heart, in cases of long duration it must lead to hypertrophy. It is well known that this occurs.

that to which clinical observation leads at the bedside. The definition of impaired compensation which we have reached on the basis of our experimental figures is, as reflection reveals, basically identical with that to which clinical consideration leads. At the bedside one speaks of impaired concentration when symptoms appear which are referable to excessive filling of the lesser circulation and venous system; whereas we [experimenters] understand by impaired compensation a diminution of our proportional figure, due either to decline of the [peripheral] arterial pressure or to rise of the pressure in the pulmonary artery. That both of these occurrences give rise to the symptoms on which clinical observation establishes the diagnosis of impaired compensation, is quite intelligible.

We omit to add further clinical considerations to these results of our experiments. With respect to this, clinical research must teach us whether and to what extent the facts of clinical observation agree with the experiments and with the conclusions derived from them.

From the results of the hemodynamic experiments that we have reported above, it follows that during artificial mitral insufficiency the blood in the lungs flows under high pressure but low gradient, since during insufficiency not only the pressure in the pulmonary artery but also that in the left atrium is elevated. As can readily be seen, this causes severe overfilling of the pulmonary vessels. In this way the conditions arise which, according to the teaching of von Basch,* may lead to swelling of the lungs and finally also to rigidity of the lungs.

This made it necessary to ascertain by direct experiment whether in actual fact the lung becomes swollen and rigid in consequence of artificial mitral insufficiency. To repeat briefly, according to the teaching of von Basch swelling of the lungs is a consequence of widening of the alveoli due to increased pressure in the pulmonary capillaries. This widening must be followed by enlargement of the internal space in the lungs. In a larger series of experiments, carried out in this same laboratory by Dr. Grossman (p. 80) in which high pressure filling of the pulmonary vessels was induced by muscarine poisoning, choking, obstruction of the left atrium, squeezing of the left ventricle and compression of the aorta, enlargement of the internal space was demonstrated clearly. Thus, these trials show that swelling of the lungs arises after intense overfilling of the lungs with blood.† It was questionable whether the degree of overfilling produced in our experiments by means of artificial mitral insufficiency is sufficient to cause demonstrable swelling of the lungs or to cause increase in their internal space . . . .

The increased pulmonary volume, von Basch's "swelling of the lungs," can surely be demonstrated during insufficiency. As our experiments show, stiffness of the lungs—in mild grades only—can also develop as a consequence of mitral insufficiency. It follows, in agreement with the hemodynamic experiments, that the filling of the blood vessels of the lung that occurs during artificially produced mitral insufficiency does not occur under very high pressure. As is shown by the subsequently demonstrated enlargement of the internal space and of the external volume of the lungs, this pressure is able to widen the alveoli but it seldom leads to such pressure on the capillaries as affects the expansibility of the lung to the extent that severe rigidity develops. We wish to emphasize that this conclusion as to the influence of mitral insufficiency on the lung is of practical importance, since it throws new light on the tendency of the patient who has mitral insufficiency to develop dyspnea. According to our experiments the lungs of a cardiac patient of this kind must be abnormally large and they are, so to speak, in a condition similar to emphysema. Therefore they are less suitable for respiration than normal lungs. This diminished suitability of the lungs does not show itself at rest in cases of fresh but clearly demonstrable deficiencies of the heart; it first makes its appearance when the action of the heart is altered by even slight degrees of effort.

Finally we must point out that enlargement of the lungs in cases of cardiac deficiency has not escaped clinical observation. In the writings which Traube left behind we find the following passage in a note titled "Emphysematous Chest in Heart Patients": "Young persons affected with organic heart disease quite often have an abnormally voluminous and vaulted thorax, together with considerable increase in the volume of the lungs . . ." We must interpret this statement of Traube as signifying that the results of our experiments on animals have their analog in man.

Comment on Experiments of Bettelheim and Kauders

The authors state that their experiments were instituted for the deliberate purpose of throwing light on the clinical phenomena observed in valvular heart disease, specifically mitral insufficiency. They point out that some of the earlier investigators who had experimented on the valves had limited their observations to measurement of carotid arterial pressure, a procedure that could hardly yield information on the behavior of the right ventricle. Salomon Stricker, however, had measured simultaneously the pressures in the pulmonary and carotid arteries. Bettelheim and Kauders, pointing out certain inadequacies in Stricker's methods, resolved to repeat the investigation while observing the pressures in both the pulmonary artery and a peripheral artery.

Since, as previous investigators had admitted, lacerations of valves produced by the blind insertion of metallic sounds were difficult to control, Bettelheim and Kauders followed Stricker's clever method of producing mitral insufficiency by fixating a cannula in the atrioventricular orifice, thereby in effect joining the atrium to the ventricle. To vary conditions, they provided their cannula with an obturator. They remark that the cannula produced not pure mitral insufficiency but insufficiency complicated by stenosis, since the instrument occupied space in the atrioventricular orifice.

Kymographs were connected to both the carotid and pulmonary arteries and special attention was paid to the ratio between the two pressures. It was found that during continuous mitral insufficiency pressure in the carotid artery tended to be reduced and that in the pulmonary artery tended to be increased. When both pressures increased the former tended to increase more. From this the inference was drawn that in clinical cases of mitral insufficiency compensation depended more on the left ventricle

† [Footnote deleted.]

than on the right. This conclusion was clearly recognized to run counter to dominant opinion. Further, it was concluded that compensation could exist in the presence of either an increased or decreased arterial pressure. This aspect of the investigation leads to a prolix discussion which it has been impossible to include in the foregoing excerpts. What is chiefly significant is that the problems of clinical disease constantly remained at the focus of the argument.

Editor's note: This is the 100th article on the history of medicine written by Dr. Jarcho for this Journal.

Tachycardia-Dependent and Bradycardia-Dependent Mobitz Type II Atrioventricular Block Within the Bundle of His

MICHAEL A. GOODFRIEND, MD
S. SERGE BAROLD, MB, FRACP, FACC

Rochester, New York

This report describes the occurrence in a young man of transient Mobitz type II and complete atrioventricular (A–V) block due to a lesion within the proximal portion of the His bundle probably caused by excessive alcohol intake. Initially A–V block was precipitated by tachycardia only but it subsequently became solely bradycardia-dependent before disappearing completely after a few days. Bundle of His electrograms demonstrated block above the site of recording of the His bundle potential.

The advent of His bundle electrocardiography has contributed greatly to our understanding of atrioventricular (A–V) conduction and has demonstrated that conduction block within the bundle of His may not be as rare as previously suspected.[1–8] In this report, we document interesting sequential changes in A–V conduction in a patient who exhibited transient second and third degree A–V block with a normal QRS complex. Bundle of His electrograms demonstrated block above the site of recording of the His bundle potential. Initially, A–V block was precipitated by tachycardia only but subsequently it became solely bradycardia-dependent (phase 4 block) before disappearing completely.

Case Report

A 27 year old man was admitted to the Genesee Hospital on April 26, 1972 because of several episodes of light-headedness during the preceding 24 hours. The patient had been in good health and took no medications, but he volunteered that he had consistently consumed very large quantities of whiskey every day for several weeks before admission in contrast to his usual intake of 12 to 15 cans of beer a week for several years. On examination, he was well nourished and afebrile. The pulse rate was 52/min and regular and blood pressure was 125/65 mm Hg. There were no signs of congestive heart failure, and no gallop sounds were audible. A very soft grade 1/6 short midsystolic murmur was heard along the left sternal edge associated with physiologic splitting of the second heart sound. No systolic clicks were detected.

Chest X-ray findings were normal. The initial electrocardiogram (Fig. 1) demonstrated sinus tachycardia (105/min) with complete A–V block and a junctional rhythm of 53/min. The QRS configuration, duration and mean frontal plane axis (+20°) were all normal. Hematologic studies, blood urea nitrogen and serum electrolytes were all within normal limits. Transient elevation of serum glutamic pyruvic transaminase levels occurred with a peak of 90 international units (normal 10 to 30 IU) in the absence of elevations of serum glutamic oxaloacetic transaminase, total and fractional lactic dehydrogenase and creatine phosphokinase levels. Serum alkaline phosphatase and bilirubin also remained within normal limits and bromsulfophthalein retention was 5 percent 45 minutes after intravenous injection of 5 mg/kg body weight. Despite the history of heavy alcohol intake, there was no clinical evidence of withdrawal symptoms. Immunologic studies (antistreptolysin O, heterophiles antibody, serum protein electrophoresis, immunoelectrophoresis, rheumatoid and antinuclear factors) and specimens for viral isolation and viral antibody titers in the acute and convalescent phases were unrevealing in the search for etiologic factors.

Electrocardiographic Findings

A marked sinus arrhythmia was intermittently present throughout the patient's hospital stay and was noted when he was both awake and asleep. Continuous electrocardiographic monitoring documented the following sequential changes in A–V conduction. (1) *Day 1:* Complete A–V block occurred with a narrow QRS complex as seen in the initial electrocardiogram (Fig. 1), in which the sinus rate is 105/min and the junctional rate 53/min. (2) *Day 2:* There were intermittent periods of tachycardia-dependent Mobitz type II A–V block[9] with a narrow QRS complex and a P–R interval of 0.18 second (Fig. 2, A and B). At this time, complete A–V block occurred only with further acceleration of the sinus rate but not with long sinus cycles (Fig. 2, F and G). (3) *Day 3:* Periods of Mobitz type II and 2:1 A–V block occurred without apparent or measurable changes in sinus rate (Fig. 2, C and E). (4) *Days 4 to 6:* Frequent periods of bradycardia-dependent Mobitz type II and high degree A–V block were recorded during periods of sinus arrhythmia only when the P–P interval lengthened to a critical value in excess of 1,280 msec, as demonstrated in Figure 3 (compare Fig. 2, F and G). Prolonged periods of ventricular asystole were repeatedly observed during sleep (Fig. 3, B to F), and normal conduction was frequently restored by arousing the patient. During this phase, the patient consistently exhibited 1:1 A–V conduction (P–R interval 0.18 second) with short P–P intervals previously associated with tachycardia-dependent block. (5) Recovery and normal A–V conduction in the second week of hospitalization were followed by complete absence of any manifestation of heart block for a follow-up period of more than 1 year.

Throughout the hospital course, the patient was treated with propantheline bromide (Pro-banthine®), 15 mg orally every 6 hours, at the insistence of his private physician. After prolonged continuous monitoring revealed apparent complete recovery of A–V conduction, the patient was discharged without a pacemaker. He has abstained completely from alcohol and has remained asymptomatic. Follow-up studies during the past 14 months have included multiple Holter monitor (Avionics) electrocardiographic tape recordings that showed no evidence of recurrent conduction abnormalities. Repeated attempts to induce A–V block by applying pressure to the carotid sinus have failed.

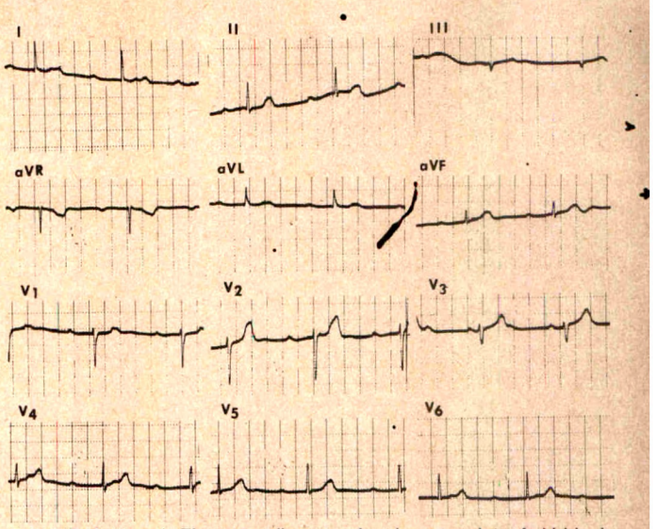

FIGURE 1. Day 1: Electrocardiogram showing complete A–V block with a sinus rate of 105/min and a junctional rate of 53/min.

Electrophysiologic Studies

On the second hospital day, His bundle electrograms were recorded by standard techniques using a no. 5F bipolar catheter with electrodes 1 cm apart. Filtered electrograms (40 to 500 Hz) were recorded on a multichannel oscilloscopic photographic recorder (DR12, Electronics for Medicine) simultaneously with surface leads I, aVF and V_1

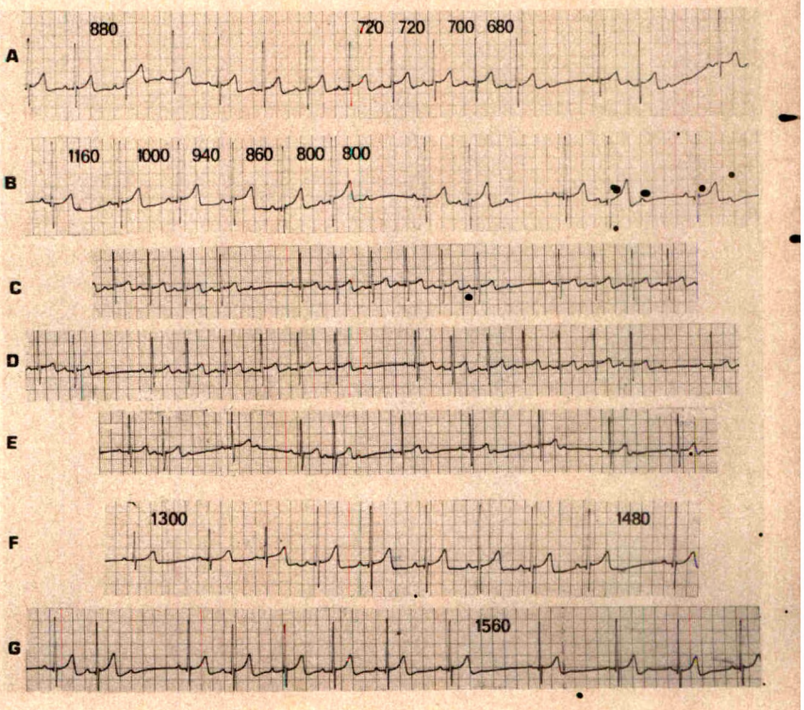

FIGURE 2. Strips **A and B** (Day 2) show tachycardia-dependent Mobitz type II A–V block. The P–R interval of 0.18 second remains constant before and after the nonconducted P waves. Strips **C to E** (Day 3) show periods of Mobitz type II and 2:1 A–V block without measurable changes in sinus rate. Similar recordings were obtained toward the end of the second day. Strips **F and G** (Day 2) show absence of A–V block when sinus arrhythmia causes marked bradycardia.

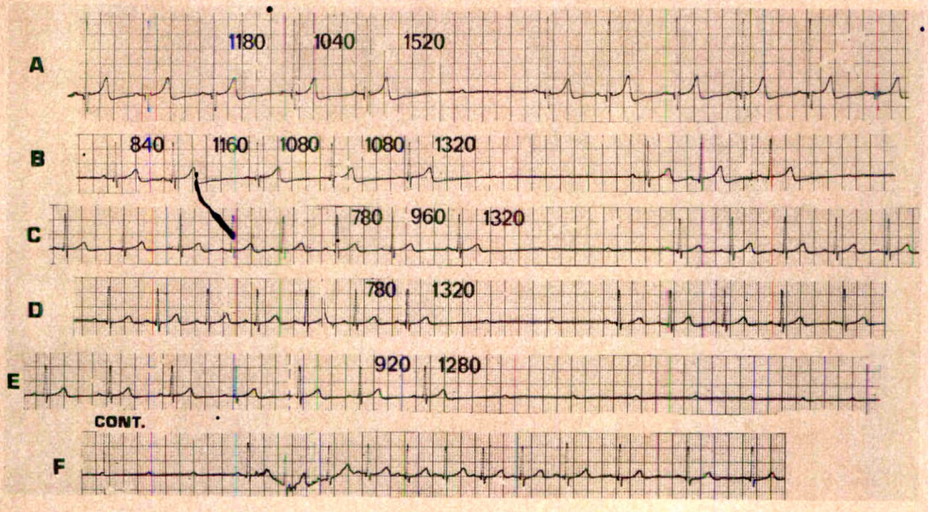

FIGURE 3. Days 4 to 6: Bradycardia-dependent A–V block. Strips **E and F** are continuous. Strip **A** shows Mobitz type II A–V block. Strips **B to F** show high degree A–V block only when the P–P interval lengthens to a critical value in excess of 1,280 msec. Note that the P–R interval (0.18 second before the dropped impulse or impulses) remains 0.18 second when A–V conduction resumes except in strip **B,** in which the P–R interval is a little longer because of an A–V junctional escape beat. Normal A–V conduction resumes at a P–P interval significantly shorter than 1,280 msec. The reason for this change is unclear but may be related to alterations in membrane responsiveness,[17] hypopolarization or repetitive concealed conduction and discharge of subsidiary pacemakers.

at paper speeds of 100 mm/sec. Intervals were measured according to the criteria of Narula et al.[3]

Figure 4, A and B, demonstrates Mobitz type II A–V block with narrow QRS complexes. The P–P interval ranges from 590 to 620 msec. The A–H time of 120 to 125 msec is slightly beyond the upper limit of normal (50 to 120 msec)[3] and is constant both before and after the blocked impulses. Duration of the His potential and the H–V interval of 40 msec are normal.[3] The absence of a His potential after the atrial deflection in nonconducted impulses localizes the block above the level of recording of the His potential and, therefore, within the A–V node or the proximal bundle of His. Figure 4C shows a segment of 2:1 A–V block. In each instance, no His bundle deflection follows the atrial potential of the nonconducted impulses. When complete A–V block occurs (Fig. 4D) the subsidiary focus appears to originate from the bundle of His as indicated by the constant occurrence of the His potential before a normally conducted QRS complex; the configurations of the His spike and the H–V interval (40 msec) remain identical compared with that of the conducted sinus impulses. Although the amplitude of the *A* wave varied throughout the recording period because of catheter movement and respiration, every conducted P wave (more than 200 were available for analysis) gave rise to a clearly visible His bundle spike with an amplitude that bore no relation to the size of the *A* wave. Therefore the consistent failure to record the His potential only after blocked *A* waves must be real and cannot be attributed to catheter movement.

Because the conduction pattern (Mobitz type II block) suggested a lesion within the bundle of His rather than within the A–V node, systematic exploration of various recording sites was carried out to search for "split" His potentials,[1,5] but none were found. Numerous attempts to pace the His bundle[10] were unsuccessful probably because of the strategic site of the lesion.

No junctional extrasystoles were noted during 6 days of continuous monitoring and no concealed His bundle extrasystoles were recorded during His bundle electrography, thereby excluding concealed extrasystoles as a potential cause of pseudo-Mobitz type II block.[8,11]

Validation of His bundle potentials has recently been the subject of lively debate.[5,12,13] We believe that in all likelihood the deflection labeled H represents His bundle depolarization rather than the right bundle (RB) potential for the following reasons: (1) Consistent recordings of a large triphasic H potential were achieved with similar H–V intervals (40 msec) upon repeated repositioning of the catheter. (2) The normal RB–V interval is less than 27 msec,[14,15] although right bundle branch disease cannot be excluded in this case. However, no terminal slurring or conduction delay was seen in lead V_1. (3) The recording of large *A* waves in the His bundle electrogram suggests the potential labeled H represents His bundle depolarization. Sizable atrial potentials are rarely seen when a large right bundle potential is recorded.[14–16]

Discussion

Bundle of His electrograms in our patient localized the site of block above the level of recording of the His potential. However, several features suggest more precise localization of the lesion within the proximal portion of the His bundle as opposed to the A–V node: (1) The P–R interval of 0.18 second remained constant and did not shorten after impulses were suddenly blocked or when stable 2:1 A–V block supervened. In contrast, when increased refractoriness causes A–V nodal block, either at constant or slightly changing P–P intervals, A–V conduction after a blocked impulse occurs with a shorter P–R interval. The P–R interval could remain constant when block occurs in the lowest part of the A–V node, but this situation must be rare clinically. (2) No Wenckebach cycles were observed during an extensive period of observation. (3) The occurrence of bradycardia-dependent block favors a lesion in which there are cells with potential automatic activity[17] (His-Purkinje system, as discussed later).

Mobitz type II A–V block: Our case clearly represents an example of type II A–V block according to the classification originally conceived by Mobitz.[9] Fifty years later, confusion still exists about the definition of Mobitz type II A–V block.[18] We believe that its use should be restricted to an electrocardiographic pattern characterized by failure of a *single* impulse to conduct to the ventricles, in the absence of antecedent progressive lengthening of the P–R intervals, which may be normal or prolonged.[7,19–21] These P–R

intervals remain constant before and *after* the blocked impulse,[8,20–22] as implied by Mobitz,[9] who indicated in his diagrams that the R–R interval encompassing the blocked impulse was twice the basic cycle length.

Previous studies have demonstrated a strong correlation between Mobitz type II A–V block with His-Purkinje system (infranodal) lesions,[3,8,23–26] but this pattern has not been established conclusively as arising within the A–V node in experimental animals or man. Recent reports have claimed that Mobitz type II block can occur proximal to the His bundle during constant or slight variations in P–P intervals,[8,27–32] but atypical type I sequences cannot be excluded in most of those reports[28–32] because the initially prolonged P–R (or A–H) interval shortened after the dropped impulse. Narula[8] recently reported the sudden occurrence of high degree A–V block (which he called Mobitz type II block) without preceding prolongation of the P–R interval in a case in which the block appeared to be above the site of recording of the H potential. However, according to the concepts of Mobitz type II block cited, only the case of Langendorf et al.[27] and the present example represent Mobitz type II A–V block with a narrow QRS in which the block is localized above the site of recording of the His potential.

Bradycardia-dependent A–V block: Our patient exhibited bradycardia-dependent A–V block presumably caused by enhanced automaticity within the His-Purkinje system[17] (phase 4 block). Many examples of bradycardia-dependent bundle branch and, more recently, fascicular blocks have been described.[33–38] Bradycardia-dependent A–V block seems to be less common but was reported in 1971 by Coumel et al.,[36] who also identified other reported cases, and more recently by Rosenbaum et al.[39] There are two types of bradycardia-dependent A–V block[36,39]: (1) permanent or stable bundle branch block associated with bradycardia-dependent block in the contralateral bundle, which result in failure of A–V conduction at critically slow rates; and (2) block proximal to the bifurcation of the His bundle associated with a narrow QRS complex, by far the rarest form.[39] Both forms of block may be paroxysmal and undetected unless spontaneous or vagally induced bradycardia elicits A–V block, or spontaneous atrial or ventricular extrasystoles precipitate block by producing relatively long postextrasystolic pauses.[39,40] In this context, atrial extrasystoles or ventricular escape beats with critical timing may also terminate A–V block and restore 1:1 A–V conduction.[39,40]

Phase 4 depolarization seems the most likely cause for bradycardia-dependent block,[17] and there are several arguments against a vagal origin in our patient: (1) The relation between periods of sinus slowing and A–V block particularly during sleep makes it unlikely that surges of vagal tone were a primary mechanism. (2) P–R intervals remained constant and did not prolong with slowing of the sinus rate, and no Wenckebach cycles were observed. Both points favor the absence of vagal influence upon A–V nodal conduction. (3) Recent microelectrode studies have demonstrated that acetylcholine, because it depresses the slope of phase 4 depolarization in the His bundle and right bundle branch of the dog, may permit conduction to proceed more rapidly.[41] Consequently, vagal stimulation might be expected to enhance rather than to slow conduction in patients with phase 4 block. The role of propantheline in determining the sequence of events in our patient cannot be assessed. The concept of phase 4 depolarization thus provides support for the hypothesis of block within the proximal bundle of His rather than within the A–V node.

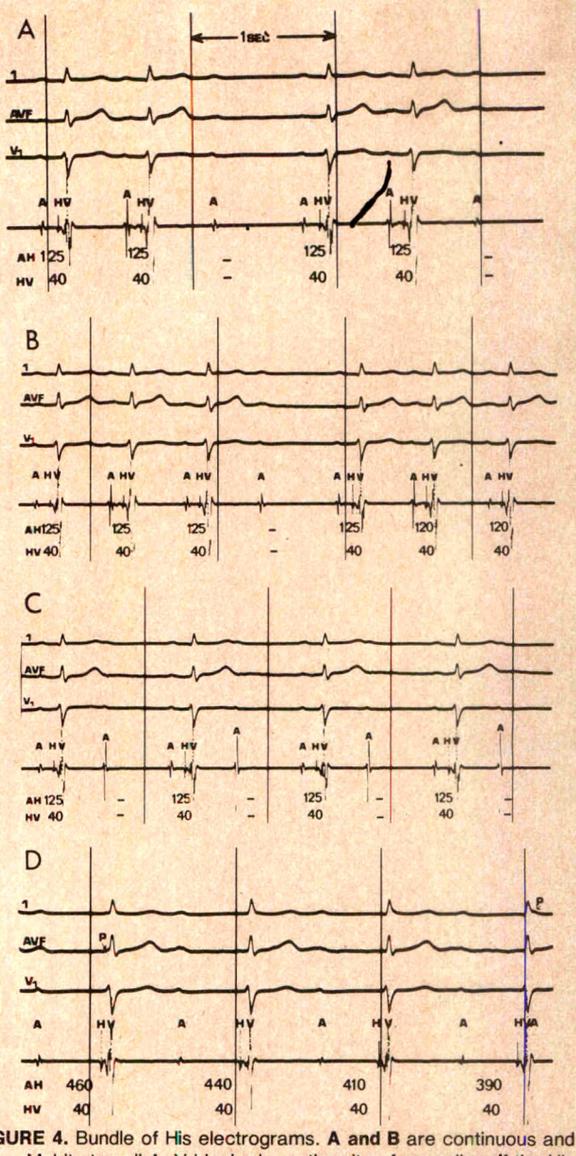

FIGURE 4. Bundle of His electrograms. **A and B** are continuous and show Mobitz type II A–V block above the site of recording of the His potential when the P–P interval measures 590 to 620 msec. **C** shows 2:1 A–V block when the P–P interval shortens to 530 msec. Note that the A–H interval of conducted beats is identical to the A–H intervals in **A and B. D** shows complete A–V block when the P–P interval shortens to 490 msec. No His spikes follow the *A* waves. Time lines = 1 second.

No specialized cells capable of spontaneous depolarization have yet been identified within the A–V node (at least in experimental animals) except for the transitional nodal-His (NH) region which has physiologic and anatomic properties intermediate between those of the A–V node and the bundle of His.[42] It would therefore be highly improbable for phase 4 bradycardia-dependent block to arise within the body of the A–V node in man.

Some cases of bradycardia-dependent conduction block have demonstrated both phase 3- (prolonged recovery)[43] and phase 4-related block either concurrently or sequentially in the same patient,[34,37–39,44] and El-Sherif et al.[38] recently succeeded in producing transient tachycardia- and bradycardia-dependent block in the right and left bundle branches and the His bundle of dogs after ligation of the anterior septal artery.

Etiology: We cannot exclude congenital A–V block as a cause, but the recent work of Ettinger et al.[45] suggests that alcohol might be important. These workers demonstrated that chronic ethanol feeding of well nourished dogs may result in prolongation of the H–Q interval and QRS complex and accumulation of a mucopolysaccharide-like material in the interstitium and dilatation of the sarcoplasmic reticulum, as observed in electron microscopic studies, in the absence of significant ventricular hypertrophy. Several of their animals died suddenly and unexpectedly, thus suggesting a possible relation to conduction abnormalities and arrhythmias. Conduction disturbances including A–V block and bundle branch block have frequently been observed in alcoholics.[46] In view of the high level of alcohol consumption and the conduction block that regressed with abstinence, ethanol must be considered an intriguing possibility for A–V block in our patient.

Bradycardia-dependent A–V block might be more common than realized and should be considered in the electrophysiologic investigation of syncope of possible cardiac origin. Interventions such as vagal maneuvers or the production of electrically induced premature atrial and ventricular beats may unmask bradycardia-dependent block.[36,39,40] The evanescent and apparently reversible clinical course of our patient suggests that the use of permanent pacing in phase 4 A–V block, particularly in young patients with a narrow QRS complex, should be considered only after an extended period of observation has excluded a potentially reversible lesion. The recent work of El-Sherif et al.[38] tends to support this view. Further follow-up studies of our patient will be required to determine whether our therapeutic decision was correct.

Acknowledgment

We are indebted to Dr. George Lovell for referring the patient to us and for his encouragement and support.

Mitral and Tricuspid Lesions Associated with Polypoid Atrial Tumors, Including Myxoma

JOHN B. CARTER, MD
RALPH CRAMER, Jr, MD
JESSE E. EDWARDS, MD, FACC

St. Paul, Minnesota
Minneapolis, Minnesota

The related atrioventricular valves in 11 instances of polypoid atrial tumors were examined grossly and histologically. Nine of the tumors involved the left atrium and, of these, seven were myxomas. The two right atrial tumors were myxomas.

Histologically evident lesions of the mitral valve were present in seven of the nine left atrial tumors. The most common change consisted of fibrous thickening of the endocardium in the angle between the left atrium and posterior mitral leaflet and fibrous thickening of the atrial surfaces of the leaflet. Less common changes were a fibrous thickening of the chordae and of the left ventricular mural endocardium in relation to chordae inserting into the posterior leaflet. The changes described were also evident at gross examination in two of the nine cases with left atrial tumors.

In the two cases of right atrial myxoma, both showed fibrous thickening of the atrial surfaces of the tricuspid leaflets; one also exhibited fibrous thickening of the right ventricular endocardium beneath the septal leaflet of the tricuspid valve.

The lesions described are considered responses to the effects of friction by the tumor upon the surfaces involved. It is significant that grossly evident lesions may evolve from this rubbing action.

Classically, left atrial myxoma is a condition associated with a normal mitral valve. Yet recent reviews have indicated that both structural and hemodynamic abnormalities of the mitral valve may be associated with this tumor.[1–6] The exact nature of the structural changes in the valve has not been described. Pilot studies by us have suggested that the mitral valvular lesions are responses to friction upon the valve by the characteristically polypoid atrial myxoma. Therefore, we undertook a study of the atrioventricular valves in hearts with several types of polypoid atrial tumors.

Case Material

Eleven specimens of hearts with polypoid tumors were available for restudy. These included nine examples of left atrial tumors — seven myxomas, one mesenchymoma and one recurrent myxosarcoma. Two specimens with right atrial polypoid tumors, each a myxoma, were also studied. The essentials of the 11 cases studied are summarized in Table I. Except for one child, aged 13 years, with a left atrial myxoma, the patients were adults ranging in age from 21 to 87 years.

Surgical excision of the primary tumor had been performed in two of the cases, a left atrial myxoma in one (Case 5) and left atrial myxosarcoma in the other (Case 9). Autopsy in both cases revealed recurrent tumor. In Case 5, the patient died of intestinal carcinoma 4 years after excision of the left atrial myxoma. The recurrent tumor was represented by a narrow, relatively long strand attached to the atrial septum (Fig. 1*a*). The size of the tumor indicated in Table I for this case is that of the surgically excised tumor; for the patient with recurrent myxosarcoma of the left atrium the size of the recurrent tumor is indicated.

This study was supported by Public Health Service Research Grant 5 RO1 HL05694 and Research Training Grant 5 TO1 HL05570 from the National Heart and Lung Institute, National Institutes of Health, Bethesda, Md. Manuscript accepted August 9, 1973.

Address for reprints: Jesse E. Edwards, MD, United Hospitals, Miller Division, Department of Pathology, 125 W. College Ave., St. Paul, Minn. 55102.

The tumors ranged in size from 2.5 by 2 to 11 by 4 cm (Fig. 1,*b* and *c*). In four the largest dimension was 4.0 cm or less; in seven the greatest dimension of the tumors ranged from 5.0 to 11.0 cm.

Except for the patients with the smaller tumors, deaths were usually attributed to the presence of the polypoid tumor. Congestive heart failure and sudden death were common manifestations of the tumor; in patients with the smaller tumors heart failure and sudden death appeared as incidental findings and were unrelated to the tumor. In one case previously reported,[7] a large right atrial myxoma was associated with diabetic Kimmelstiel-Wilson disease (Case 11) (Fig. 1*d*).

For each of the 11 hearts, standard gross examination was performed with particular emphasis upon the nature, location and size of the tumor as well as the condition of the atrioventricular valve homolateral with the tumor. Each of the valves involved was also examined histologically.

Samples for histologic study of the atrioventricular valves were taken as follows. For the mitral valve, a section was taken of its posterior leaflet, the related chordae tendineae and left atrial and ventricular walls. Sections of the tricuspid valve were taken through two zones, the septal and the anterior leaflets, each including the related right atrial and ventricular walls and chordae tendineae. For each sample, a slide was stained with hematoxylin-eosin and another with Lawson's elastic tissue counterstained with the van Gieson's connective tissue stain.

TABLE I
Summary of Data in 11 Cases Studied

Case no.	Age (yr) & Sex	Tumor Size (cm)	Histologic Lesions of Related A–V Valve
	Myxoma of Left Atrium		
1	59M	2.5 × 2	0
2	68F	2.5 × 2.5	+
3	42F	4 × 3	+
4	87F	4 × 3.5	+*
5	68M	5 × 5	+
6	42M	6 × 6	+
7	13F	11 × 4	0
	Mesenchymoma		
8	26F	6 × 4	+
	Recurrent Myxosarcoma		
9	21F	6 × 5	+*
	Myxoma of Right Atrium		
10	Adult(?)	3 × 2	+
11	61F	10 × 5	+

* Gross lesions also present.

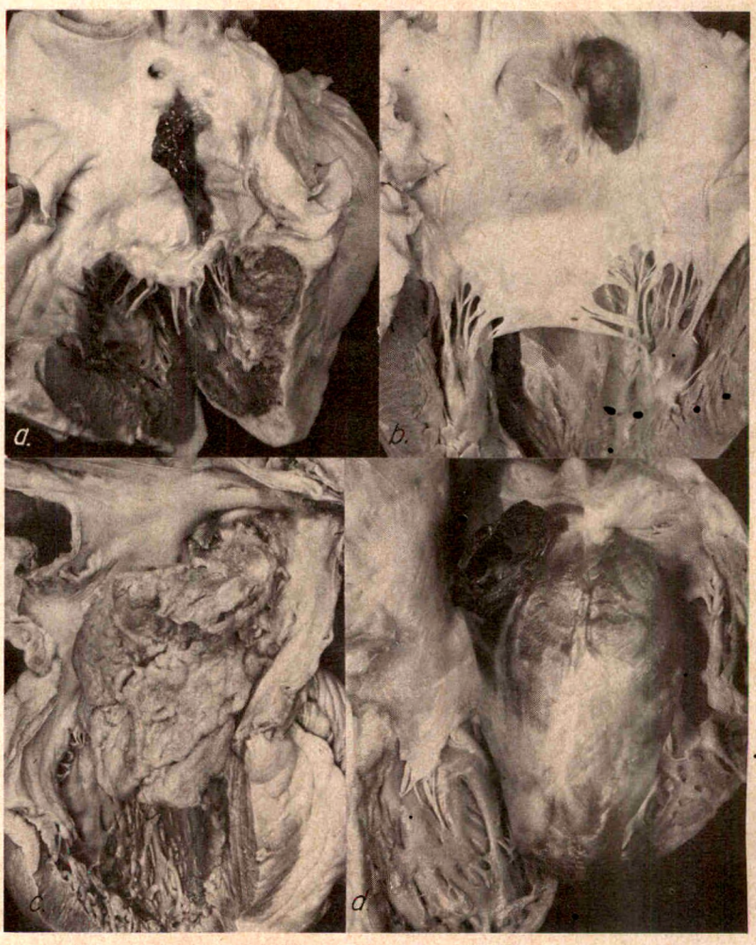

FIGURE 1. a, Case 5. Recurrent left atrial myxoma 4 years after excision of the primary tumor. The recurrent tumor is represented by a cylindrical gelatinous strand attached to the atrial septum. **b,** Case 1. The smallest left atrial myxoma in the series. No lesions of the mitral valve were present histologically. **c,** Case 7. The largest left atrial tumor in the series, from a 13 year old girl, showing a myxoma attached to the atrial septum. The tumor protrudes through the mitral valve and presents in the left ventricle. The mitral valve was devoid of lesions. **d,** Case 11. The larger of the two right atrial myxomas. The tumor is attached by a pedicle to the atrial wall and extends through the tricuspid orifice into the right ventricle.

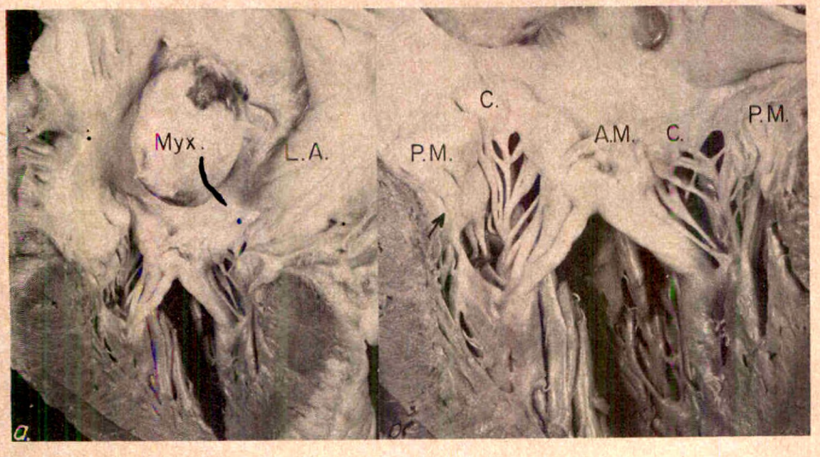

FIGURE 2. Case 4. Calcified left atrial myxoma associated with fibrosis of mitral valve. **a,** polypoid myxoma (Myx.) is attached to septal wall of the left atrium (L.A.). The mitral valve is abnormal. **b,** close-up view of mitral valve showing marked fibrosis of line of closure of anterior leaflet (A.M.) and of central chordae. There is sparing of the commissures (C.) and commissural chordae. The posterior mitral (P.M.) leaflet is fibrotic; its chordae are entrapped in fibrous tissue **(arrow)** of the related left ventricular wall.

Results

Gross Examination

Grossly, the semilunar valves were normal in each case as was the atrioventricular valve contralateral to the side of the atrial tumor. Gross abnormalities were noted in the mitral valve in one case with a calcified left atrial myxoma (Case 4) and another with left atrial recurrent myxosarcoma (Case 9). The more severe changes, fibrosis of the leaflets without commissural fusion, occurred in the former case. The chordae related to the commissures were relatively thin; the remaining chordae were thickened with fibrous tissue and interadherent. The left ventricular mural endocardium related to the chordae of the posterior leaflet was thickened with engagement of related chordae in the mural fibrous tissue (Fig. 2). The second instance with gross changes involved the case of recurrent polypoid left atrial myxosarcoma (Case 9).* The abnormalities of the mitral valve, although qualitatively like those in Case 4, were less severe and there was lack of left ventricular mural fibrosis (Fig. 3).

* The details related to recurrence of the tumor in this case are being reported elsewhere.[8]

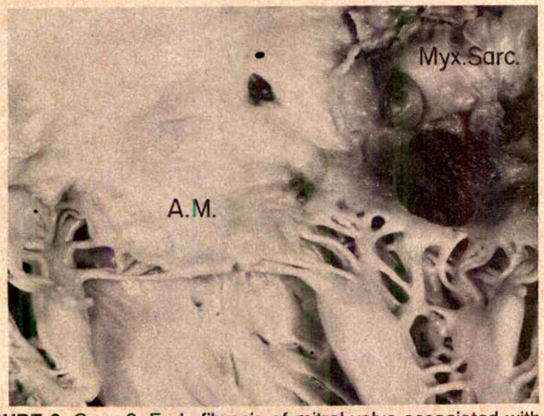

FIGURE 3. Case 9. Early fibrosis of mitral valve associated with pedunculated myxosarcoma (Myx.Sarc.) of left atrium. Diffuse thickening of the anterior mitral leaflet (A.M.) and chordae is evident.

Histologic Examination

In describing the results of histologic examination, we will consider the mitral valve first, then the tricuspid valve. None of the cases demonstrated abnormality of the myocardium except for invasion by tumor in the case of recurrent myxosarcoma.

Mitral valve: The following is a consideration of the mitral valve in nine cases of polypoid tumors involving the left atrium. The progressive disease leading to grossly visible abnormalities may be understood from changes observed in cases without grossly evident lesions. Some histologic abnormalities were noted in seven of the nine mitral valves studied; the two cases without lesions were examples of left atrial myxoma. When lesions were present, certain specific areas were involved (Fig. 4 and 5). The first of these areas was the endocardium in the angle between the posterior mitral leaflet and the left atrial wall. Six of the seven cases with lesions of the mitral valve noted histologically showed such a localization. The characteristic change was collagenous and elastic tissue thickening of the endocardium. Another common site for involvement was the atrial aspect of the valvular leaflets, seen in five of the seven cases. Surface fibrous thickening of chordae was observed in two cases and one, that with the more severe gross changes, showed fibrous thickening of the left ventricular mural endocardium in relation to chordae that attached to the posterior mitral leaflet (Fig. 5*b*). In this case, chordae were adherent to the mural fibrous tissue. In exceptional situations fibrous thickening of the left atrial wall was noted lying above the angle with the mitral valve.

The pathogenesis of the fibrous lesions described could be explained by observations among the several cases (Fig. 6). The first process appeared to be deposition of fibrin upon the endocardial surface. This was followed by fibroblastic proliferation and, finally, by maturation of the connective tissue with formation of elastic tissue.

Tricuspid valve: Neither of the two cases with right atrial myxoma showed lesions upon gross examination, but each showed histologic abnormalities. In each, there was fibrous thickening of the atrial sur-

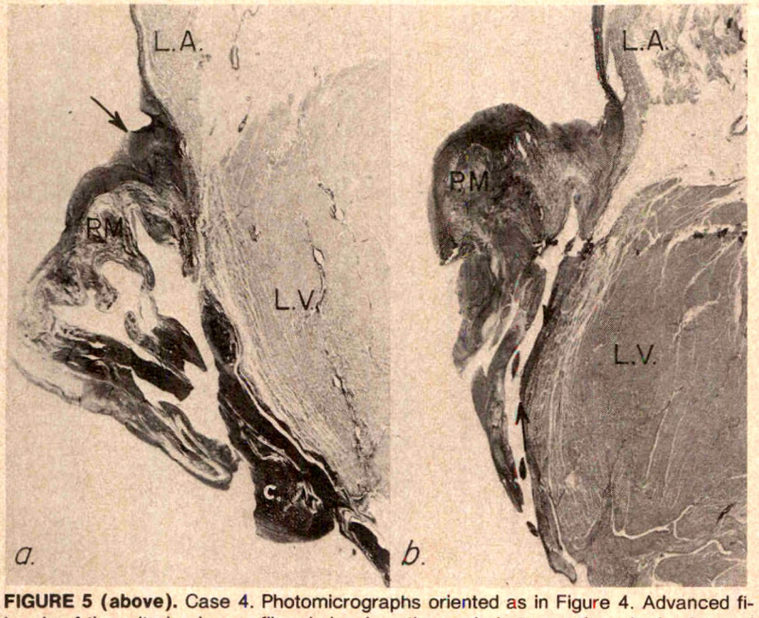

FIGURE 5 (above). Case 4. Photomicrographs oriented as in Figure 4. Advanced fibrosis of the mitral valve. **a,** fibrosis involves the angle between the mitral valve and left atrium as well as atrial and ventricular surfaces of leaflet and surfaces of chordae (c.). Elastic tissue stain × 2.5, reduced by 20 percent. **b,** additional changes include fibrous thickening (between vertical arrows) of left ventricular mural endocardium. Elastic tissue stain × 3.7 reduced by 20 percent.

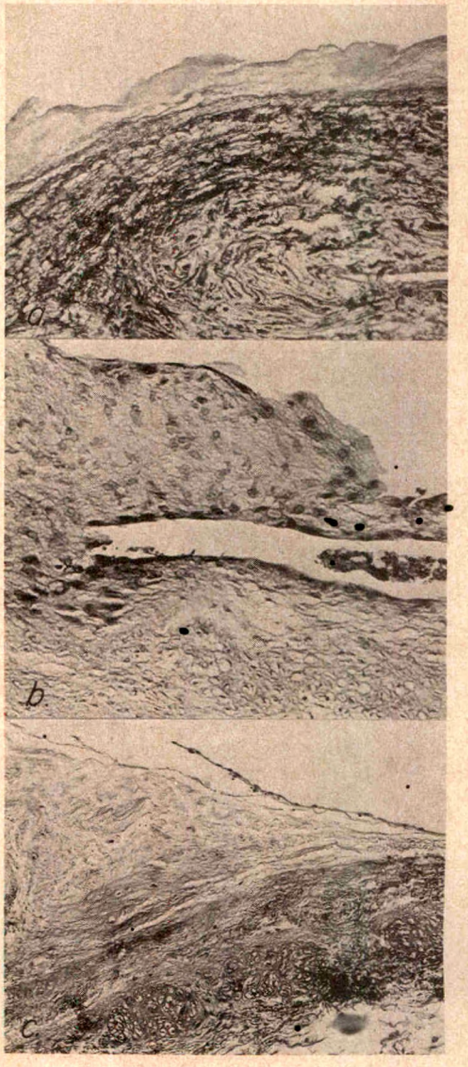

FIGURE 6 (right). Histogenesis of fibrous lesions. **a,** fibrinous deposit upon surfaces of valve (upper part of illustration). Elastic tissue stain × 47. **b,** fibrous proliferation. Hematoxylin-eosin × 50. **c,** collagenous formation. Elastic tissue stain × 50. All reduced by 16 percent.

faces of the leaflets. Additionally, in one (Case 11), there was fibrous thickening of the right ventricular mural endocardium beneath the septal leaflet (Fig. 7).

Comment

In reported cases[9,10] describing mitral valve disease in association with left atrial myxoma, the mitral disease has been considered rheumatic in origin. This assumption might be used to support the old view that left atrial myxomas are actually thrombi, a hypothesis that favors the mitral disease as primary and the "atrial myxoma" as a secondary thrombus. However, current evidence strongly supports the view that atrial myxoma is an entity different from a thrombus.[11] If one accepts the atrial myxoma as a separate entity and the mitral disease as rheumatic in origin, one is faced with coincidental unrelated conditions.

Nature of the mitral and tricuspid valve lesions: Our studies support a different concept, namely, that the mitral lesions are secondary to the traumatic effects of the tumor. We believe these lesions to be "friction lesions," that is, a reaction to rubbing of tissues by the atrial polypoid tumor. Highlights of our observations supporting this concept are: (1) None of the cases in our series showed evidence of Aschoff bodies, either healed or acute; (2) the peculiar pattern of developing fibrosis in these cases, particularly at the angle between the mitral valve and left atrial wall, is consistent with a reaction to friction by the tumor (rheumatic lesions do not possess this peculiar localization) (Fig. 8); (3) the gross anatomic features are characterized by absence of commissural fusion with remarkable preservation of the commissures and related chordae (the most severe changes were present in the mid-portions of the leaflets, whereas in rheumatic mitral disease commissural lesions are prominent); and (4) lesions of the tricuspid valve in instances of right atrial polypoid tumor are qualitatively like those of the mitral valve when a polypoid tumor is present in the left atrium.

The lesions described, which are considered friction lesions, should be added to other endocardial friction lesions that have been described from our laboratory. These are (1) lesions of the right ventricular endocardium in relation to chordae tendineae of the septal leaflet of the tricuspid valve in instances of left ventricular hypertrophy,[12] and (2) lesions of the left ventricular endocardium in relation to chordae tendineae of the posterior mitral leaflet in cases with hooding of the mitral valve.[13]

Explanation for absence of mitral valve lesion in two cases: Of the two left atrial tumors without mitral valve lesions, one tumor was the smallest in the series (Case 1), and the other the largest (Case 7). One may explain the absence of lesions in Case 1 on the basis of the small size of the tumor, which may not have extended to the level of the mitral valve. Absence of lesions in the case with the largest tumor might be explained by the soft gelatinous consistency of that tumor. It is of interest and in support of our view that the most severe lesions were observed in the one case with a calcified myxoma (Case 4).

Others[6] have mentioned the traumatic effects of atrial myxoma on the mitral and tricuspid valves, but a systematic study of pathologic changes in these valves has not been made. Mitral insufficiency associated with atrial myxoma has been abolished by surgical plication of the valve leaflet.[3,4,9] The cases in the present series did not include an example of mitral or tricuspid incompetence although such a phenomenon is recognized as a possibility.

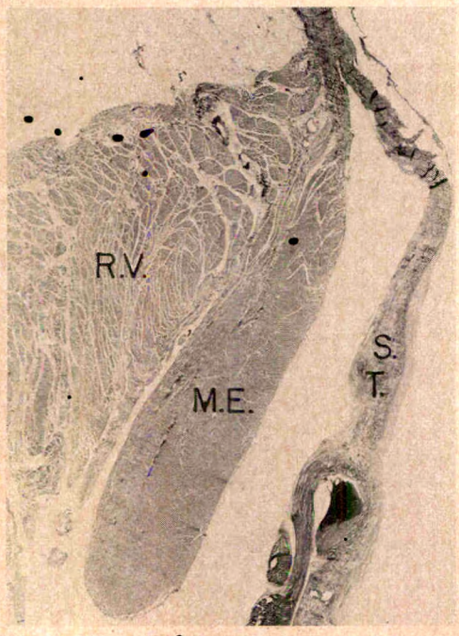

FIGURE 7 (left). Case 11 (from case illustrated in Figure 1*d*). Photomicrograph of septal tricuspid leaflet (S.T.) and related right ventricular wall (R.V.). Mural endocardium (M.E.) of the latter is thickened. Elastic tissue stain × 6.7.

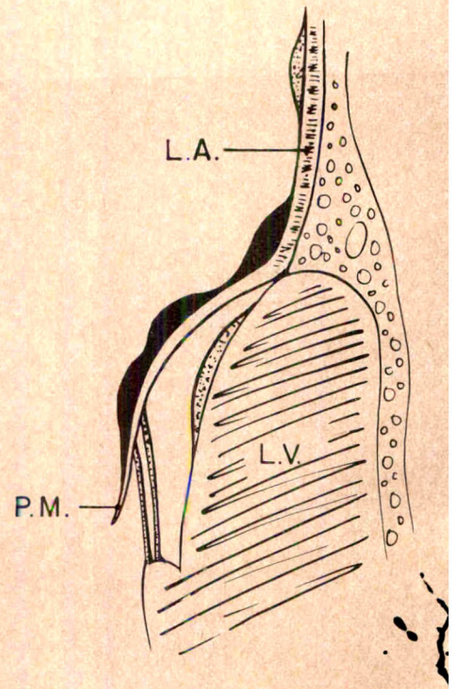

FIGURE 8 (right). Diagrammatic portrayal of sites of fibrosis in relation to mitral valve. **Black areas** indicate areas of most common and heaviest fibrosis. **Lighter shaded areas** of chordae, atrial wall and subvalvular left ventricular endocardium are less commonly involved. L.A. = left atrium; L.V. = left ventricle; P.M. = posterior mitral leaflet.

Caseating Granulomas of the Heart

T. STERLING CLAIBORNE, MD

Atlanta, Georgia

A 49 year old woman died suddenly having had known rheumatic mitral valve disease and severe rheumatoid arthritis for many years. Several calcified masses within her myocardium proved on autopsy to be caseating granulomas almost certainly due to tuberculosis.

Tuberculosis of the heart is rare and to judge from published reports, it is becoming even less frequent. Because of increasingly better control of tuberculosis, this is to be expected. In 1939, Custer and Charr[1] reviewed 14,493 deaths due to tuberculosis and found 64 cases of tuberculosis of the heart. Norris,[2] in 1904, observed 6 cases of tuberculosis of the heart in 1,764 patients who died of tuberculosis. In Poland it was recently reported[3] that one case of cardiac "caseous tumor" was found in 20,000 autopsies.

Pathologically, three types of tuberculosis of the heart are fairly well distinguishable: (1) miliary tuberculosis, in which the heart is among the organs involved; (2) diffuse infiltrating interstitial disease; and (3) caseating nodular disease (tuberculoma). Miliary tuberculosis of the heart is by far the most frequent; tuberculomas are much rarer. The heart may contain one or more tuberculomas.[4–6] The lesions may involve the atria, the ventricles or the ventricular septum,[7] and may extend from a pericardial focus. Tuberculomas may lead to heart block[8] or other abnormal rhythms,[9] and have been reported to lead to myocardial rupture[10] or right ventricular outflow tract obstruction.[11] In this report we present a case of caseating granuloma of the heart.

Case Report

The patient, a white woman, died in July 1972 at age 49 years. She had been followed up by the author from age 12 years. At age 10 (1934) she had scarlet fever, followed by a persisting illness with albuminuria and evidence of acute nephritis. In 1936, a diagnosis of subacute glomerulonephritis and rheumatic fever with mitral valve disease was made. Systolic and diastolic murmurs were heard in the mitral area. Her condition improved after bed rest, but evidence of mitral stenosis and insufficiency remained and the left atrium was noted to be enlarged in 1940.

In December 1942, she married and subsequently had a normal pregnancy and was delivered of a son in December 1943. in 1946 she had a bothersome cough accompanied by a low grade fever. Chest X-ray films were normal, blood cultures were negative as were studies for lupus erythematosus. A specific diagnosis was never made, although her problem was thought to be a persisting bronchial infection after repeated upper respiratory infections.

In 1950 her thyroid became enlarged and classic symptoms of thyrotoxicosis developed. After a partial thyroidectomy in 1951, her condition improved.

In 1953 arthritis developed and progressed to severe crippling rheumatoid disease. This appeared to be related to a respiratory infection with bronchitis. Despite the rheumatic heart disease and rheumatoid arthritis, she had a second pregnancy and was delivered of a boy; there were no complications. In 1956 she had clinical and laboratory evidence of recurrent hyperthyroidism which was alleviated after treatment with propylthiouracil. She continued to

Dr. Claiborne is Clinical Professor of Medicine, Emory University School of Medicine, Atlanta, Ga. Manuscript accepted August 20, 1973.

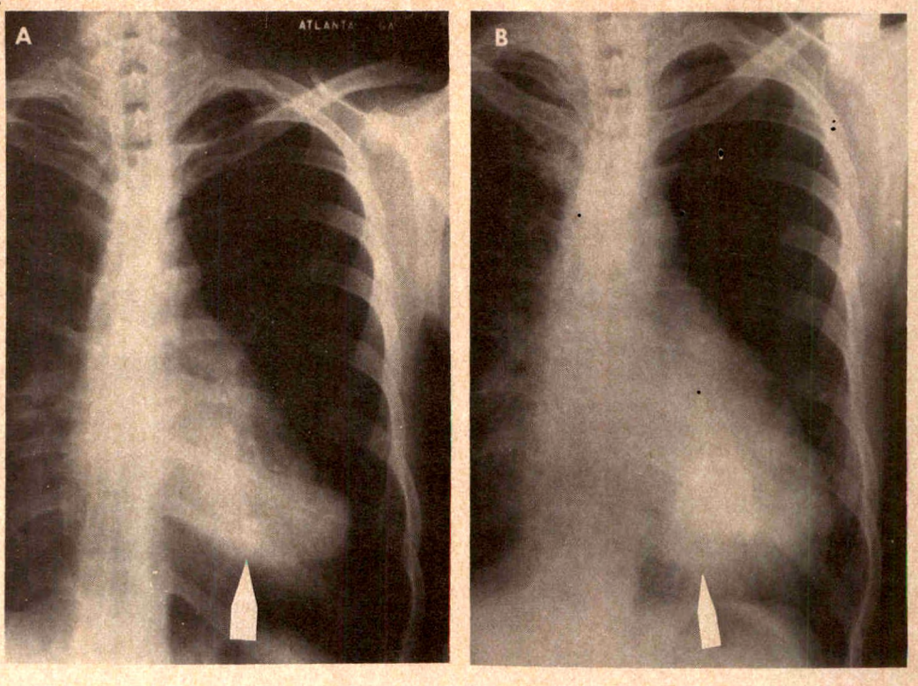

FIGURE 1. Chest roentgenograms showing area of calcification in left ventricle **(arrow). A,** December 30, 1957. **B,** August 10, 1971.

receive small doses of this medication until her death; her serum protein-bound iodine levels remained normal. One year later she was hospitalized because of the severe rheumatoid arthritis and for the first time calcification was noted in the left ventricle near the mitral valve (Fig. 1A). It was assumed to be calcification in the mitral annulus. She received small doses of prednisone over a 30 day period, followed by large doses of salicylates. In retrospect, it was noted that during this period her father underwent bronchoscopic examination and was found to have basal bronchiectasis; a sputum culture was positive for M. tuberculosis. In 1958 the patient was again hospitalized with severe rheumatoid arthritis. Her axillary and epitrochlear lymph glands were enlarged, and she also had rheumatoid nodules on the olecranon. She was referred to a rheumatologist who gave her prednisone therapy for 3 weeks and then began treatment with gold salts which was continued through 1961. The lymph nodes receded in size.

Cardiac catheterization findings: In 1969 it became obvious that the calcium in the heart was not associated with the mitral annulus and that two distinct calcified areas were present. Cardiac catheterization with angiography was performed on August 14, 1969 by Dr. Arnoldo Fiedotin at St. Joseph's Infirmary, Atlanta, Ga. The summary of his report is as follows: "Calcific mass involving the epicardium and myocardium of the lateral aspect of the left ventricle, producing extrinsic total obstruction of the atrioventricular branch of the circumflex, with collateral opacification of the distal atrioventricular branch of intracoronary collateral vessels from both the anterior descending and circumflex coronary artery. Very minimal irregularities of arteriosclerotic nature in the initial aspect of the circum-

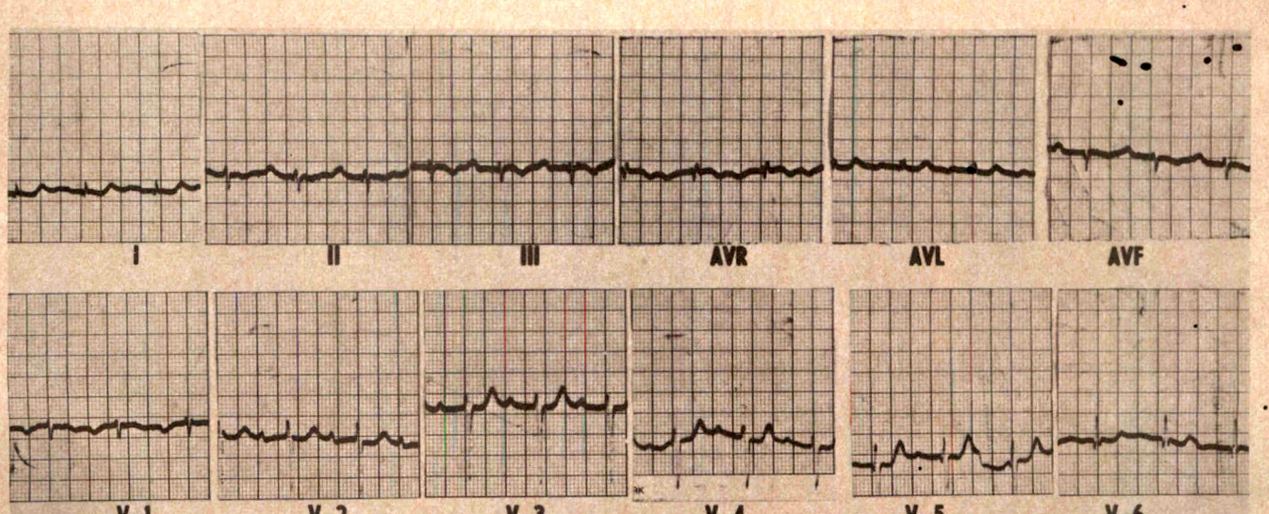

FIGURE 2. Electrocardiogram obtained August 6, 1970 showing a prolonged P–R interval, low voltage of the QRS complex and small R waves in leads III and aVF.

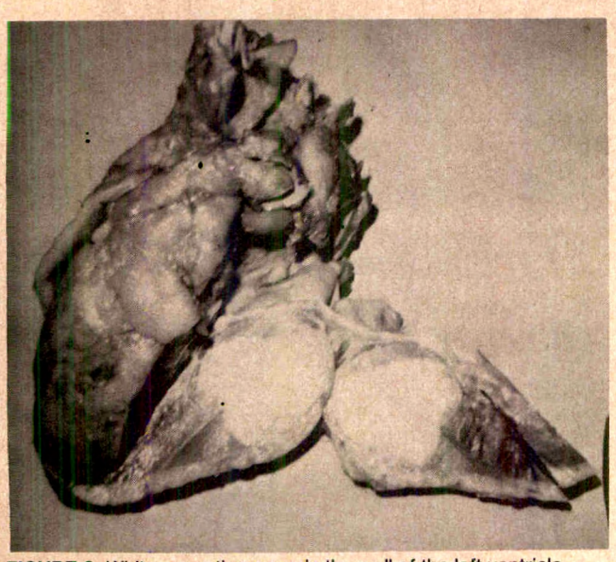

FIGURE 3. White caseating mass in the wall of the left ventricle.

flex coronary artery. Rheumatic heart disease with moderate noncalcific mitral insufficiency and mild mitral stenosis. A second area of calcification is apparent in the anterior pericardium overlying the right ventricular apex and interventricular septum." A chest X-ray film taken on August 10, 1971 (Fig. 1B) showed that the major area of cardiac calcification was larger than in 1969. The patient did quite well despite severe arthritis until her death in 1972 which occurred suddenly, without warning, while she was preparing to eat lunch.

It is interesting to note that the P–R interval in the patient's electrocardiograms became gradually prolonged over a 34 year period. Representative measurements (in seconds) are as follows: 0.16 (1936), 0.20 (1951), 0.22 (1954), 0.24 (until 1962), 0.26 (until 1969) and 0.30 (1970). The electrocardiogram also showed a gradual loss of the R wave in leads III and aVF during this period. (Fig. 2).

Pathologic findings: Autopsy was performed by Dr. John T. Godwin at St. Joseph's Infirmary, Atlanta. The mechanism of death was not determined. The heart weighed 600 g. Moderate mitral stenosis and mitral insufficiency were present. The pericardium was adherent to the lateral surface of the left ventricle beneath which was an area of grayish white pultaceous material measuring 4.2 cm in diameter (Fig. 3). It extended to, but did not involve, the endocardium. The grayish white material was surrounded by dense fibrous tissue (Fig. 4). A smaller but similar area was found in the right ventricular wall. The adherent pericardium contained several smaller caseating nodules. There was also a 0.3 by 0.4 cm nodule in the lower lobe of the right lung. No tuberculosis organisms were seen in, or cultured from, these lesions. The pathologist reported, "Although this lesion has the characteristics of a chronic granuloma such as tuberculosis, one cannot make an absolute diagnosis in view of the absence of positive culture material or lack of organisms in tissue stains."

Discussion

Although no tubercular organisms were demonstrated in either the lungs or the heart of the patient,

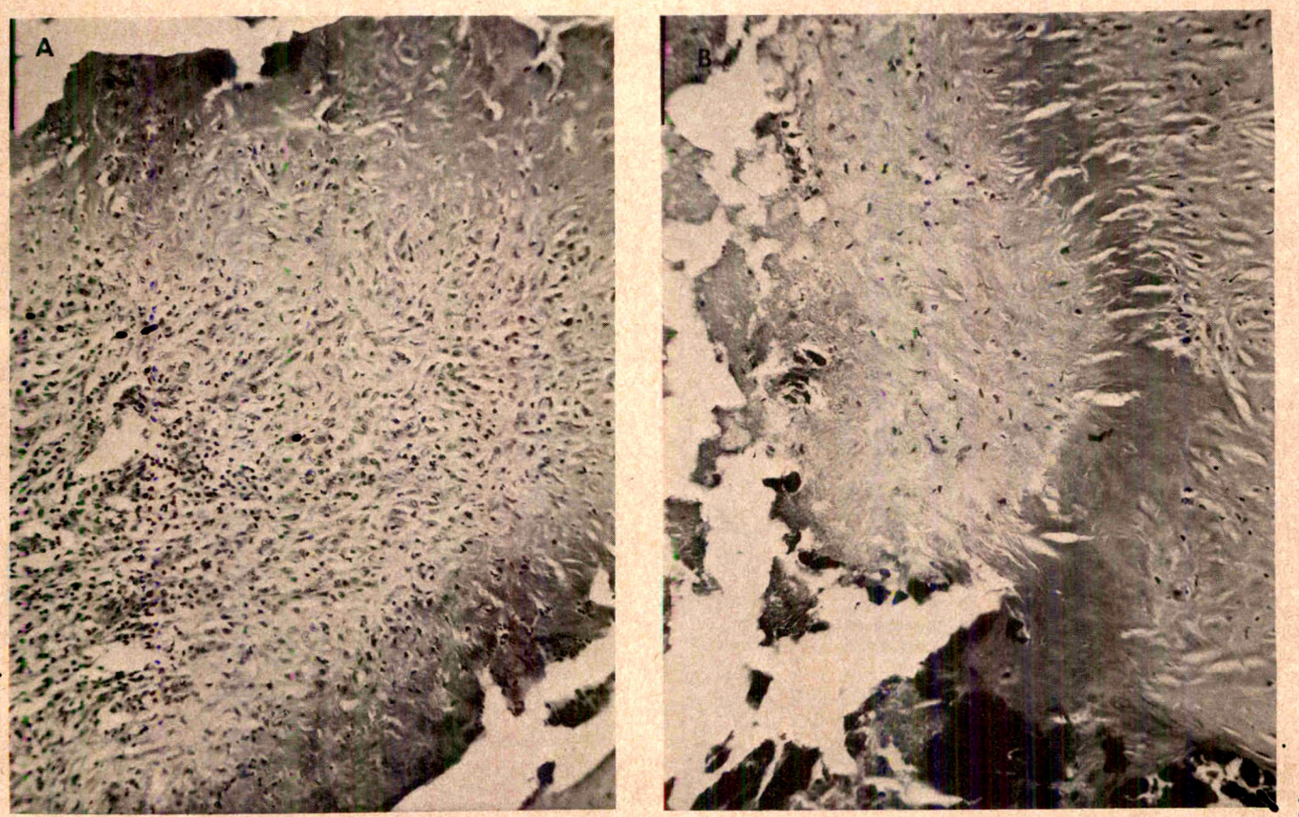

FIGURE 4. Photomicrographs of granulomas. (Hematoxylin-eosin ×200, reduced by 3 percent.)

the granulomas and the smaller nodular caseating areas were typical of tuberculomas. Other types of granulomas seem unlikely in this case. There was no laboratory or clinical evidence of syphilis. The granulomas of rheumatoid disease are much smaller than the myocardial granulomas demonstrated in our case and they do not show extensive caseation. This patient was closely associated with her father who had a bronchial washing positive for tuberculosis. In retrospect a lymph node biopsy in 1958 might have been helpful in making a diagnosis in the case.

The cause of death of the patient is not clear. It occurred suddenly and without premonitory signs to her family close by. She did not have evidence of emboli, congestive heart failure or cerebral hemorrhage at autopsy. We know that there was extrinsic pressure on the circumflex coronary artery by the large granuloma. The electrocardiogram showed the P–R interval increasing in length over a period of 34 years, and R waves were small or absent in leads III and aVF for several years. Although there was no evidence of coronary thrombosis at autopsy, insufficiency of flow may have led to complete heart block or rapid myocardial insufficiency.

Emergency Thrombectomy for Acute Coronary Bypass Graft Occlusion

J. EDWARD OKIES, MD
RICHARD P. ANDERSON, MD

Portland, Oregon

Emergency thrombectomy of occluded aortocoronary saphenous vein bypass grafts was successfully performed in two patients. Thoracotomy and thrombectomy were required in one patient to terminate a fatal arrhythmia. Coronary angiography preceded thrombectomy in another patient who had an acute myocardial infarction postoperatively. Coronary angiography should be performed when signs and symptoms of myocardial ischemia reappear in the immediate postoperative period; if an occluded graft is found, thrombectomy should be performed.

Relief of angina pectoris after coronary bypass grafting is usually prompt and often dramatic. The mortality and morbidity rates associated with this operation are exceedingly low in many centers.[1–3] However, myocardial infarction is a recognized complication of the coronary bypass operation[2]; it may result in inability to terminate cardiopulmonary bypass successfully or cause death from the low cardiac output syndrome within a few hours or days after operation.[2,4] Serious arrhythmias are also seen with myocardial ischemia and can result in death if not promptly treated.[4] The sudden reappearance of myocardial ischemia during the early postoperative period is an uncommon event that suggests malfunction of a graft carrying a critical blood supply to the heart.

This report concerns two patients who had symptomatic occlusion of a bypass graft during early convalescence; both were successfully treated by emergency operative thrombectomy.

Case Reports

Case 1

A 50 year old real estate developer had been incapacitated by severe angina pectoris for 6 months. Coronary arteriography showed 90 percent stenosis of the proximal left anterior descending artery and occlusion of a dominant right main artery. The right posterior descending artery was opacified through collateral vessels from the left coronary arterial injection. At operation, saphenous vein bypass grafts were inserted into the left anterior descending and right posterior descending coronary arteries and intraoperative mean graft flows of 120 and 60 cc/min, respectively, were measured. On the 5th postoperative day unheralded ventricular fibrillation developed. The patient's ventilation was supported and circulation maintained by external cardiac massage. Fifteen separate attempts at defibrillation (400 watt/sec) were unsuccessful despite normal levels of blood pH, PO_2, serum potassium, and a systolic blood pressure of 80 mm Hg. Emergency bedside thoracotomy revealed an occluded right saphenous vein graft. Three additional attempts at internal defibrillation (30 watt/sec) were unsuccessful. While open chest cardiac massage was being performed, thrombectomy of the graft and the posterior descending artery was accomplished using a balloon-tipped catheter introduced through a small incision in the vein. Vigorous pulsations were present in the graft after closure of the venotomy, and the heart was easily defibrillated. The circulation became immediately stable, and the patient

was moved to the operating room. Upon inspection of the graft, some remaining thrombus was palpated in a cul-de-sac adjacent to a valve near the aortic anastomosis. This portion of the graft was revised without reinstituting cardiopulmonary bypass. After reanastomosis the mean graft flow measured 30 cc/min. The wound was irrigated with saline and antibiotic solution and closed. Ventricular arrhythmias occurred for the next 10 days but were controlled medically. Electrocardiograms did not show evidence of an infarction. Convalescence was prolonged by a wound infection requiring drainage and debridement on several occasions with eventual wound healing. Coronary arteriography 5 months after operation demonstrated a functioning left anterior descending graft and an occluded posterior descending graft. The patient is alive 2 years after operation and has had no recurrence of angina.

Case 2

A 50 year old refrigerator repairman had a diaphragmatic wall myocardial infarction 12 months previously, followed by progressively increasing angina pectoris on exertion. He became unable to work because of chest pain. Coronary arteriograms were obtained which showed an 80 percent stenosis of the left anterior descending artery with retrograde filling of the distal portion of an occluded right coronary artery through collaterals. Coronary bypass grafts were inserted in the left anterior descending and the distal right main coronary arteries. Mean graft flows were 60 and 20 cc/min, respectively. The patient was walking about the ward on the 8th postoperative day when he experienced precordial pain with neck and arm radiation and diaphoresis. His circulation remained stable. Electrocardiograms revealed sinus tachycardia (120 beats/min) and S–T segment elevation in precordial leads V_2 through V_5 that was not present previously. He was moved to the cardiac catheterization laboratory where arteriography demonstrated patency of the right graft but occlusion of the left graft and, in addition, occlusion of the mid-portion of the left anterior descending coronary artery (Fig. 1A). At repeat surgery, within several hours of the onset of the symptoms, the left anterior descending graft was found to be completely thrombosed beginning in the mid-portion at a site where a large side branch of the vein had been ligated leaving a 3 mm stump. Proximally the graft was patent. Under cardiopulmonary bypass the graft was opened and the thrombus extracted from the graft and from the left anterior descending artery using a balloon-tipped catheter, establishing both antegrade and retrograde flow in this vessel. The cul-de-sac containing a large side branch was excised and the graft reanastomosed at this point. The postoperative course was uncomplicated. The electrocardiogram revealed evolution of an anterior-inferior myocardial infarct associated with mild elevation of serum isoenzyme levels which returned to normal within 5 days. Three weeks after reoperation, coronary arteriography showed both grafts to be patent (Fig. 1B). The patient is presently alive and free of angina 9 months after operation.

Discussion

Symptomatic occlusions of aortocoronary bypass grafts are uncommon in the immediate postoperative period and the 2 patients described in this report represent the only instances seen in more than 150 patients operated upon at the Portland Veterans Administration Hospital during the past 3 years. In general, occlusion of a coronary bypass graft is heralded by the onset of recurrent angina pectoris within a few

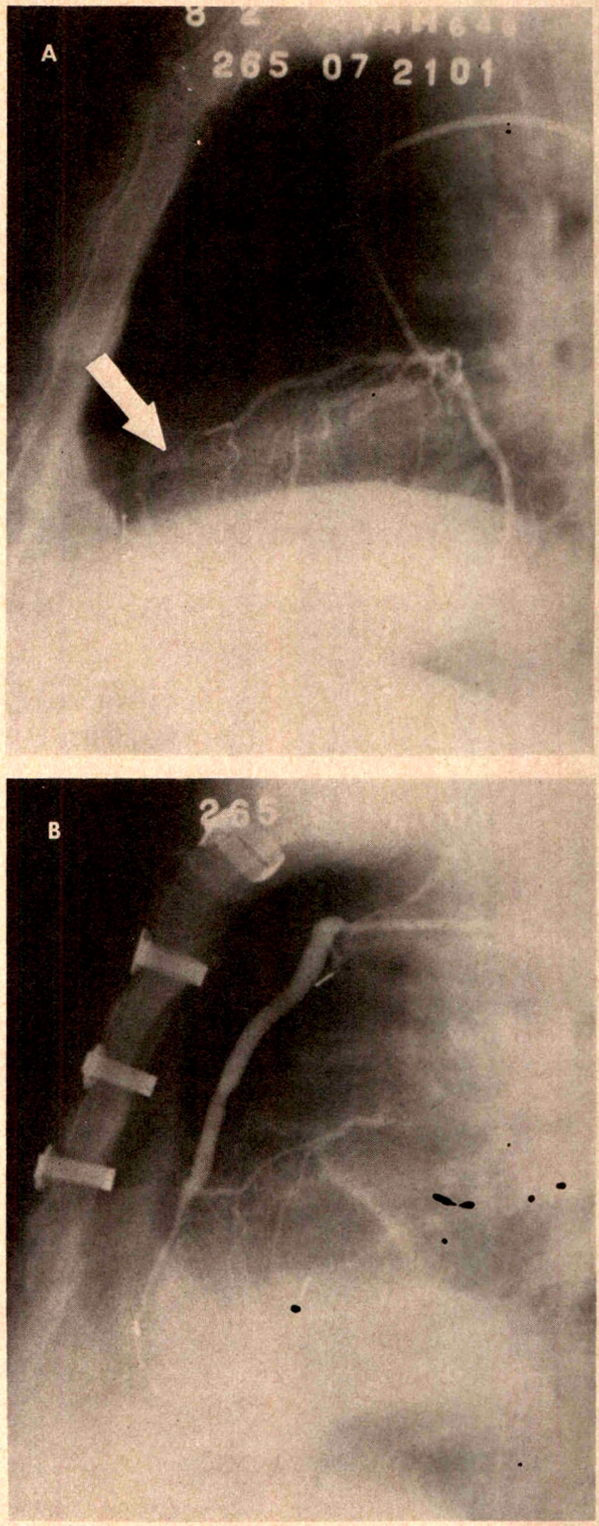

FIGURE 1. Case 2. **A,** left coronary angiogram demonstrating occlusion of the mid-portion of the left anterior descending artery at the anastomotic site **(arrow).** The vein graft was not visualized. At reoperation, thrombus extended from the distal vein graft into the left anterior descending artery. The vein graft to the right coronary artery was patent.

months of operation.[1] Serious arrhythmias and myocardial infarction would seem to be more likely when a graft supplying an obstructed coronary artery without much collateral circulation fails[2] or when thrombus from an occluded vein graft extends into the coronary artery and further interrupts blood flow to a portion of the myocardium that is already compromised because of proximal coronary artery disease. This latter situation occurred in both of our patients.

Causes of early graft occlusion: Many factors have been held responsible for early occlusion of coronary bypass grafts including position and redundancy of the graft, its distortion by development of fibrous adhesions, excessive tension on the anastomosis, and injury to the vein graft itself.[5–7] Other factors include poor runoff of the distal coronary bed[8] and discrepancy of size between the saphenous vein and the coronary artery to which it is anastomosed.[9] Technical factors may have been partly responsible for the thrombosis in our patients. Proximity of a venous valve to the aortic anastomosis appeared to be the origin of thrombus in the graft of the first patient. A cul-de-sac created by failure to ligate a large side branch flush with the vein wall was the origin of thrombus in the second patient. In each case a combination of turbulence and stasis of blood as a result of the cul-de-sac was probably the cause of clot formation and eventual propagation.

Treatment of early graft occlusion: Occlusion of a graft in itself may not be a catastrophic or even a clinically recognizable event in a patient after bypass surgery.[10] However, patients who have sudden reappearance of symptoms and signs of myocardial ischemia in the immediate postoperative period should be considered candidates for emergency coronary arteriography to assess the patency of vein grafts and the coronary arteries to which they are anastomosed. If an occlusion can be demonstrated, the patient should be reoperated upon, thrombectomy of both the vein graft and coronary artery performed, and the precipitating cause of the thrombosis corrected. Thrombectomy was necessary in both of our patients and resulted in termination of a fatal arrhythmia in one and cessation of acute ischemia in the other.

Theoretically, technical factors resulting in early occlusion of aortocoronary bypass grafts can be eliminated. However, an awareness of the possibility of early thrombosis of the vein graft must be maintained, and an aggressive approach taken by both the medical and surgical staff to afford patients the opportunity for prolonged survival and a more complete relief of symptoms.

Right Ventricular Function in Acute Myocardial Infarction

CHARLES E. RACKLEY, MD, FACC
RICHARD O. RUSSELL, Jr., MD, FACC

Birmingham, Alabama

Right ventricular function has been evaluated by the measurement of right atrial or central venous pressure in many experimental and clinical studies. The assumption that the function of the right and left ventricles was similar led to the use of the central venous pressure as a measure of left ventricular performance.[1] Clinically, central venous pressure has been used to estimate the effective blood volume and the adequacy of ventricular filling in conditions of acute hypovolemia and septic shock. In patients with acute myocardial infarction the central venous or right ventricular end-diastolic pressure may be increased, and this finding has been interpreted as evidence of impaired left ventricular function as well as increased venoconstriction and peripheral vasoconstriction.[2,3] The increase in central venous pressure in myocardial infarction may depend not only on the severity of impairment of the left ventricle, but also on the involvement of the right ventricle.[2,4] The papers by Guiha, Cohn and their colleagues[5,6] recently published in this Journal propose additional considerations in the evaluation of right ventricular function in patients with acute myocardial infarction. Their observations suggest that impaired right ventricular function can result from a right ventricular infarction.

For many years it was considered that the left and right ventricles functioned in parallel fashion and that disparate performance of the two ventricles could not occur without massive pulmonary edema or circulatory collapse. Henderson and Prince[7] demonstrated in the isolated cat heart that increased left atrial pressure would produce a larger ventricular output than increased right atrial pressure. Opdyke et al.[8] recorded simultaneous right and left atrial pressures in animals before and after rapid infusion of saline solution. They concluded that left atrial pressure was consistently greater than right atrial pressure, and that the left ventricle was a less elastic structure than the right ventricle. Additional experimental investigations, studies in chronic heart disease and observations in patients with acute myocardial infarction have demonstrated that right atrial pressure cannot be used to evaluate left ventricular diastolic filling pressure.[9–11]

Separation of the levels of right and left ventricular performance was demonstrated experimentally by Case et al.[4] These investigators reduced left coronary flow and produced a depressed left ventricular function curve while the right ventricular function curve maintained a normal ascending slope. Figure 1 illustrates disparate function of the left and right ventricles in a patient with an acute inferior myocardial infarction. Left ventricular filling pressure was measured as pulmonary arterial end-diastolic pressure and right ventricular filling pressure recorded as right atrial pressure. Low molecular weight dextran was rapidly infused while cardiac output and ventricular filling pressures were measured. The stroke work index for each ventricle was calculated and related to the filling pressure to construct ventricular function curves.[12] The right and left ventricular function curves in this patient confirm the existence of unilateral depression of left ventricular performance with impaired coronary blood flow.[13]

Starr and colleagues[14] were unable to produce increases in venous pressure after extensive damage by cautery to the right ventricle of experimental animals. From their study it was concluded that an isolated right ventricular infarction might not produce augmented central venous pressure. The paper of Guiha et al.[5] provides additional experimental data on right ventricular damage and demonstrates that with volume overloading the ventricular function curve of the right ventricle is significantly lower than that of the left ventricle. Their studies suggest that a stress such as volume overload may be required to demonstrate the depressed function of the damaged right ventricle.

Wartman and Hellerstein[15] in their review of 2,000 consecutive autopsies recorded right ventricular infarction in 22 (13.8 percent) of 164 cases of myocardial infarction. In 4 instances there was isolated right ventricular infarction and in the remaining 18 examinations there was either extension of left ventricular infarction into the right ventricle or a combination of right and left ventricular infarctions. Wade[16] reviewed the pathogenesis of right ventricular infarction in 19 hearts studied post mortem and reported

Address for reprints: Charles E. Rackley, MD, Department of Medicine, University of Alabama Medical Center, University Station, Birmingham, Ala. 35294.

that the right coronary artery was occluded in 18 instances. The major anatomic lesion was damage to the posterior wall of the right ventricle. In addition, right ventricular infarction tended to occur in hypertrophied hearts exhibiting ischemic disease. The electrocardiographic changes of right ventricular infarction were usually those of an inferior or posterior wall myocardial infarction, but these changes may not be sufficiently specific to permit an accurate clinical diagnosis of right ventricular infarction.

The mechanism for the low incidence of right ventricular infarction in coronary artery disease was attributed for many years to the thebesian theory advocated by Blumgart et al.[17] This theory maintained that the right ventricle possessed an extensive thebesian system that could provide retrograde flow through the thin right ventricular wall. This hypothesis was eventually discarded, and the mechanism was ascribed to a combination of the reduced metabolic needs of the right ventricle and the effects of decreased pressure on the coronary collateral circulation.

Although increased central venous pressure in patients with inferior myocardial infarction had prompted previous investigators to consider right ventricular infarction, the report by Cohn et al.[6] describes the clinical diagnosis of right ventricular infarction. As reported earlier by these investigators[18] in hemodynamic studies on circulatory shock, massive pulmonary emboli were usually associated with increased pressures in the right heart chambers at a normal left ventricular end-diastolic pressure. However, in their recent paper the presence of inferior wall infarction and the negative results of studies for pulmonary emboli raised the possibility of right ventricular infarction, which was confirmed at autopsy in several patients. Furthermore, the recognition of right ventricular infarction carries clinical significance since the selected form of therapy may be different from that for pulmonary emboli. Blood volume expansion and the reduction of systemic afterload proved beneficial in several of the patients described.

The experimental, pathologic and clinical observations on right ventricular infarction in man suggest that the mechanism is frequently extension of the left ventricular infarction into the free wall of the right ventricle. Figure 2 shows the right and left ventricular function curves of a patient who sustained both anterior and inferior wall myocardial infarctions. After volume expansion with low molecular weight dextran, there was marked depression in the right ventricular function curve associated with a depressed left ventricular function curve and a descending limb. Therefore, in a patient with cardiogenic shock and increased central venous pressure one should consider infarction of the left ventricle

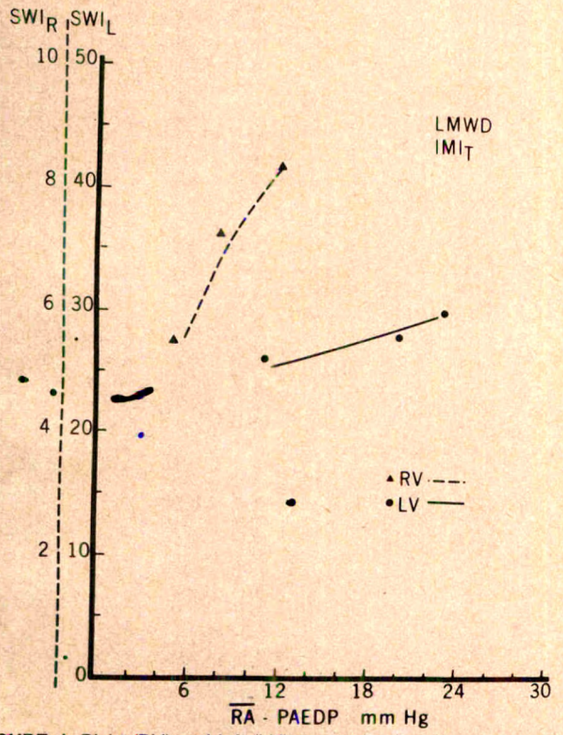

FIGURE 1. Right (RV) and left (LV) ventricular function curves after infusion of low molecular weight dextran (LMWD) in a patient with an acute transmural inferior myocardial infarction (IMI$_T$). The right ventricular function curve demonstrates a normal ascending slope; the depressed left ventricular function curve indicates impaired ventricular performance. PAEDP = pulmonary arterial end-diastolic pressure; $\overline{RA}$ = mean right atrial pressure; SWI$_L$ and SWI$_R$ = stroke work index of the left and right ventricles, respectively.

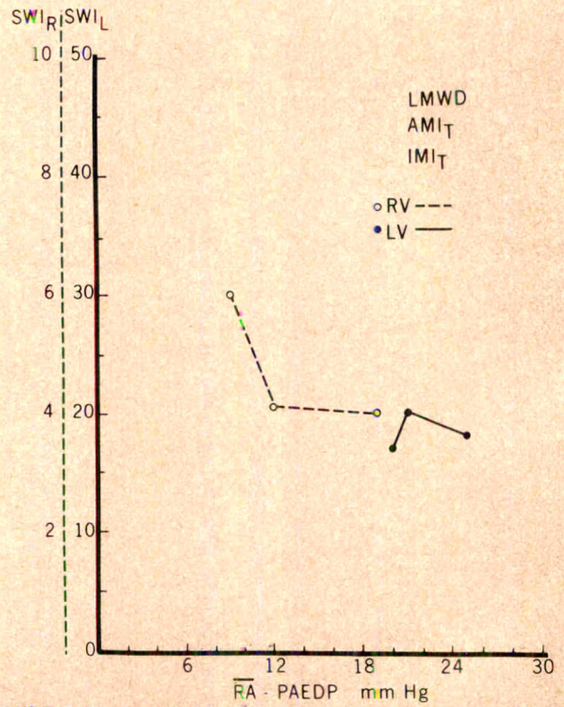

FIGURE 2. Right and left ventricular function curves in a patient with acute transmural anterior (AMI$_T$) and inferior (IMI$_T$) myocardial infarctions during blood volume expansion with low molecular weight dextran. The descending limb of the left ventricular function curve indicates severe impairment of left ventricular performance, and the descending right ventricular function curve suggests extension into the right ventricular wall. Abbreviations as in Figure 1.

with extension into the right ventricle as a diagnostic possibility. Preexisting hypovolemia may mask impaired left ventricular function, which can be further delineated with volume expansion. Under these conditions the left ventricular filling pressure will often increase much more rapidly than right ventricular filling pressure. Usually in massive pulmonary embolism the left ventricular end-diastolic pressure will be normal. Therefore, a depressed left ventricular function curve in the presence of shock and increased central venous pressure should suggest damage to the left as well as the right ventricle.

In summary, analysis of right ventricular function in acute myocardial infarction should consider not only the strain on the right ventricle resulting from left ventricular failure and increased pulmonary arterial pressure, but also the possibility that the left ventricular infarction has extended into the free right ventricular wall. Right ventricular infarction remains clinically and pathologically infrequent, and experimental studies suggest that right ventricular infarction must be an extension from the left ventricle rather than isolated right ventricular damage for depressed function of the right ventricle to occur. A central venous pressure exceeding an abnormally increased left ventricular filling pressure or a depressed right ventricular function associated with a depressed left ventricular function curve should suggest extension of the left ventricular infarction into the right ventricle. Since the clinical evaluation and analysis of the electrocardiogram are not sufficiently sensitive for the diagnosis, right ventricular infarction may be recognized more readily from hemodynamic measurements and assessment of right and left ventricular function. The potentially beneficial therapeutic response to blood volume alterations and vasodilator therapy warrant consideration of right ventricular infarction in this setting as delineated in the papers by Dr. Guiha and associates[5] and Dr. Cohn and co-workers.[6]

EMERGENCY MYOCARDIAL REVASCULARIZATION

The article by Cheanvechai et al. on emergency myocardial revascularization[1] may be subject to misinterpretation. Two points are worthy of careful examination.

First, the 100 patients "were classified *retrospectively* according to preoperative and serial postoperative enzyme levels." They were classified on the basis of this retrospective classification into two groups as follows: (1) impending myocardial infarction, and (2) acute myocardial infarction. The authors acknowledge the difficulty of making this distinction except retrospectively but fail to recognize the bias introduced when classification is done by hindsight. For example, they state that 6 of the 26 patients with "early phase myocardial infarction" were studied during crescendo angina, and "signs of acute infarction developed during these studies." In addition, the remaining 20 of the 26 had an acute myocardial infarction 3 hours to 7 days after arteriographic studies were performed. It is possible that the arteriographic studies might have contributed to the evolution of a myocardial infarction. Thus, these patients could be considered to have had a complication of angiography. However, with this retrospective classification system, the possibility of a laboratory complication is a logical impossibility.

Second, the authors state that if saphenous vein bypass graft is successful in the group of patients with preinfarction angina, acute myocardial infarction and its sequelae will be averted. Of the 63 patients with impending myocardial infarction who were operated upon, 4 died and 6 had a postoperative myocardial infarction. This is a 15.8 percent complication rate in this group of patients who are supposedly being operated upon to prevent myocardial infarction and its sequelae. No one really knows the true instance of myocardial infarction and death in patients with this syndrome of impending myocardial infarction. At the time I write, there are no published prospective studies dealing with the natural history of this group of patients defined by clinical, electrocardiographic, physiologic and angiographic criteria to compare with data in a similar surgically treated group.

REPLY

Dr. Conti's letter underscores the difficulties in terminology of acute coronary syndromes and the problems in classifying patients who may be candidates for emergency surgical intervention.

Our classification of patients into the groups of *impending* myocardial infarction or *acute* myocardial infarction was carried out primarily on the basis of symptomatology (intensity and duration of pain, associated hemodynamic sequelae) and electrocardiographic changes that existed at the time of the decision to proceed with the operation. Serum enzyme values were rarely helpful at the time of the decision; therefore, this information was useful only in a retrospective sense. The clinical impression of impending versus acute myocardial infarction was essentially prospective in these patients.

If one hopes to salvage myocardium by early surgical intervention in acute ischemic episodes, it would serve no useful purpose to delay the operation by even a few hours until serum enzyme determinations could be accomplished. The time interval during which myocardium could be salvaged probably varies among patients depending upon several factors including total versus incomplete arterial occlusion, availability and adequacy of collateral protection, and the metabolic requirements of the myocardium.

In the group with impending myocardial infarction, there were six patients who showed evidence of infarction postoperatively and who might well have been included in the acute infarction group by preoperative categorization; however, this was not the clinical impression at the time of surgical intervention in these patients. If one were to add these 6 patients to the infarction group as well as the 4 patients from the "impending" group who died, the infarction group would have consisted of 47 patients with six deaths, a mortality of 12.8 percent, still considerably under that from acute myocardial infarction currently reported from intensive care units in most centers. Postoperative angiographic studies were performed in three of these six patients sustaining postoperative myocardial infarctions. All grafts were patent, and two patients had normal left ventriculograms. The third patient had minimal impairment of the left ventricle. We believe that major myocardial damage was prevented by the bypass grafts in this particular group of patients.

It is, of course, possible that infarction may have been related in some way to arteriographic studies carried out 3 hours to 7 days previously; but in only six patients studied during crescendo angina did signs of acute infarction develop *during* the angiographic study. The cause and effect relation between arteriography and subsequent infarction in the remaining 20 patients is speculative. At the time of surgery, none of these patients had signs of mechanical trauma to the coronary arteries.

We agree completely that the assessment of these results is seriously hampered by the lack of a suitable comparison group with similar arteriographic findings and a similar clinical judgment of impending versus acute myocardial infarction at a critical time of decision. Unfortunately, most clinical diagnoses of acute myocardial infarction are also *retrospective.*

ANALYSIS OF POSTEXTRASYSTOLIC BEATS IN THE DIAGNOSIS OF IDIOPATHIC HYPERTROPHIC SUBAORTIC STENOSIS

The degree of left ventricular outflow tract obstruction in idiopathic hypertrophic subaortic stenosis is characteristically variable and depends mainly upon two hemodynamic determinants: the size of the left ventricular cavity and the contractile state of the left ventricular myocardium.[1–3] The analysis of the postextrasystolic beat has been very useful in the diagnosis of this lesion. Because of postextrasystolic augmentation in the force of the left ventricular contraction, obstruction to left ventricular outflow increases after a premature contraction, which results in a paradoxical reduction in the arterial pulse pressure.[4] This sign has been found consistently in idiopathic hypertrophic subaortic stenosis, although occasionally the lesion is manifested only by a lack of the expected postextrasystolic widening of the arterial pulse pressure rather than by its actual decrease.[1] The width of the pulse pressure of the postextrasystolic beat has been found to be the most reliable sign in distinguishing those patients with true idiopathic hypertrophic subaortic stenosis from those who manifest nonobstructive pressure differences due to catheter entrapment at the left ventricular apex.[5]

The obstruction to the left ventricular outflow in idiopathic hypertrophic subaortic stenosis is maximal during the late ejection phase of ventricular contraction because of the progressive apposition of the hypertrophic septal musculature and the anterior leaflet of the mitral valve as the left ventricular cavity decreases in size. This phenomenon explains the typical arterial pulse contour seen in this condition, which consists of a percussion wave of rapid upstroke, followed by a delayed and decreased tidal wave.[6,7] It would be reasonable to expect that an increase in the degree of obstruction occurring during the postextrasystolic beat would be likely to affect mostly the tidal wave portion of the arterial pulse—not necessarily affecting the percussion wave—and thus the diagnosis of idiopathic hypertrophic subaortic stenosis may be overlooked if the percussion wave alone is analyzed.

We recently studied two patients believed to have idiopathic hypertrophic subaortic stenosis on the basis of typical echocardiograms[8] and the presence of a variable outflow gradient at rest that increased with the Valsalva maneuver and isoproterenol infusion; in both cases the diagnosis was confirmed by left ventriculographic findings, but the central aortic pulse tracings failed to show a narrowing of the pulse pressure in the postextrasystolic beat (Fig. 1). On further analysis it was evident that, although the percussion wave pressure of the postextrasystolic beat was considerably wider than that of the control beat, the tidal wave was markedly smaller; this phenomenon coincided with a significant increase in left ventricular pressure and the development of a large outflow tract gradient in late systole. It seems apparent that in the presence of relatively mild obstruction, the vigorous early systolic ventricular impulse that follows a premature beat is transmitted largely unimpeded to the aorta, to be suddenly curtailed later in systole

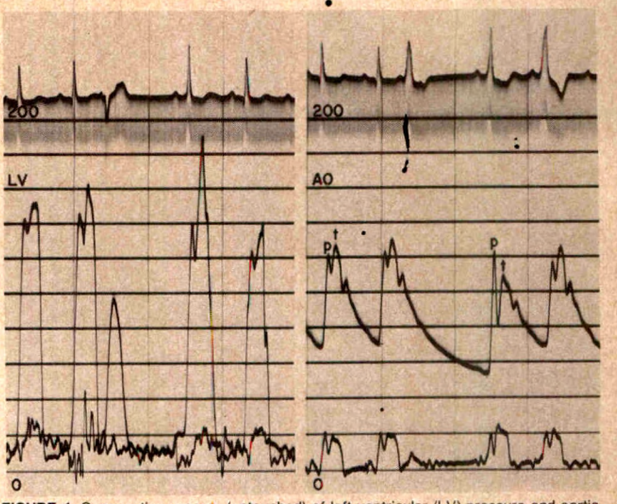

FIGURE 1. Consecutive records (untouched) of left ventricular (LV) pressure and aortic (AO) pressure in a patient with idiopathic hypertrophic subaortic stenosis. After a premature ventricular beat, the left ventricular pressure increases because of an increase in outflow obstruction. The aortic percussion wave (p) of the postextrasystolic beat is wider than that of the control beat, but the tidal wave (t) is markedly decreased. The pulmonary arterial pressure tracing is shown at bottom.

by the development of outflow narrowing as the ventricle continues to eject, and thus a decrease in the arterial tidal wave occurs.

We conclude that in the analysis of the postextrasystolic beat the components of the arterial pulse merit individual consideration and an isolated decrease in the tidal wave after a premature beat is a valid indication of the presence of idiopathic hypertrophic subaortic stenosis even if the overall pulse pressure of the postextrasystolic beat is widened as the result of an increased percussion wave.

BOOK REVIEWS

CARDIAC ARRHYTHMIAS. TWENTY-FIFTH HAHNEMANN SYMPOSIUM, edited by Leonard S. Dreifus and William Likoff. New York, Grune & Stratton, 1973, 650 pages, $29.75

Only in the past decade has the development of new techniques begun to open the door to the mysteries surrounding many arrhythmias. This volume, consisting of 650 pages and 49 articles, admirably covers the numerous recent advances in both the electrophysiology of the arrhythmias and the clinical application of these findings to diagnosis and treatment.

The symposium fulfills its purpose and does not attempt to be a complete textbook; for example, the basic diagnostic features of each arrhythmia are not presented and there is no specific chapter on arrhythmias in myocardial infarction, His bundle electrocardiography or "sick sinus syndrome." These latter subjects are discussed in one or more articles, and the arrangement of the material in sections, the detailed table of contents and the adequate bibliography facilitate the location of any topic.

The book is divided into seven sections with some overlapping, and, inevitably, some duplication. The longest and most detailed section covers the pathophysiology of impulse formation and conduction. There are comprehensive sections on Wolff-Parkinson-White syndrome, atrioventricular conduction, subjunctional conduction and pacemakers. Individual articles, which can be highly recommended, discuss the combined actions of antiarrhythmic drugs, recognition of premature systoles arising in the Purkinje system and the treatment of intractable arrhythmias.

This volume offers authoritative and well presented material in a field in which basic knowledge and therapy are often limited and tentative. Various theories and points of view are offered and, although this approach sometimes requires detailed reading, the results will be rewarding to the cardiologist.

Harry Jaffe, MD
New York, N. Y.

CIRCULATORY PHYSIOLOGY: CARDIAC OUTPUT AND ITS REGULATION, second edition, by A.C. Guyton, MD, C.E. Jones, MD, T.G. Coleman, PhD. Philadelphia, WB Saunders, 1973, 556 pages

The second edition of this book maintains the tradition of excellence established by the earlier edition. The authors have written a text that is clear and relevant to many of the issues facing physicians in their clinical practice. Important research advances of the past decade are outlined with references readily available. The background of and techniques of testing methods for obtaining cardiac output are detailed in an expanded and scholarly section.

A major contribution appearing in this edition is a two chapter section dealing with qualitative application of computer analysis. The reader is slowly led through what, at first glance, appears to be an electronic quagmire only to find that he is on the other side and on very firm footing. From this firm base, cardiac output regulation in specific physiologic and pathologic states is discussed.

This volume will undoubtedly be the principal reference source on this subject for physicians. This book gives to the medical student, cardiology resident and practicing cardiologist the basic physiologic understanding needed to handle all cardiac problems.

Calendar of Continuing Medical Education Programs

The National Committee for Continuing Medical Education, William Likoff, MD, FACC, Chairman, announces the following calendar of programs.

Each program is designed to enlarge knowledge and clarify the endlessly changing frontiers which mark scientific achievements in the recognition and treatment of cardiovascular disease. Although the disciplined objective of each program as well as its content, format and faculty are primarily determined by the Program Director, the National Committee for Continuing Medical Education always exercises the prerogative of final review and approval, whether the program is sponsored solely by the College or in collaboration with universities, colleges, hospitals and various other professional societies.

Subject matter reflects national interest and needs in the fields of patient care, research and teaching. The program structures vary in method of education.

The National Committee for Continuing Medical Education in the College earnestly solicits the interest of member and nonmember physicians alike in continuing education for the clear reason that participation provides a unique opportunity to deepen one's understanding of heart disease, the most formidable and challenging health problem of our time.

Programs and faculty are subject to change. For further information write Mary Anne McInerny, Director, Department of Continuing Education Programs, American College of Cardiology, 9650 Rockville Pike, Bethesda, Md. 20014.

To be arranged individually	**Preceptorships in Cardiology.** Arthur Selzer, FACC, director. Pacific Medical Center, San Francisco, Calif.
To be arranged individually	**Cardiology and the Problem Oriented System: A Preceptorship in the Practical Use of the System.** J. Willis Hurst, FACC, director. Emory University School of Medicine, Atlanta, Ga.
SEPT. 9–11	**A Symposium on Cardiovascular Nursing.** Fred D. Ownby, FACC and Leo Schamroth, FACC, co-directors. University of Tennessee at Nashville, Nashville, Tenn.
SEPT. 12–14	**Mechanisms and Therapy of Cardiac Arrhythmias.** Leonard S. Dreifus, FACC, director and Yoshio Watanabe, FACC and Edward K. Chung, FACC, co-directors. Marriott Motor Hotel, Philadelphia, Pa.

SUBJECT INDEX: VOLUME 33

A wave amplitude, left ventricular, after myocardial infarction, 370
Abstracts of papers of 23rd Annual Scientific Session, American College of Cardiology, 121
  addendum to, 452
  author index to, 181
  subject index to, 185
Action potential, effects of bretylium tosylate and quinidine on, 633
Actomyosin and physical training in rats, 744
Adenosine triphosphatase and physical training in rats, 744
Aerobic capacity
  after physical training, 765
  exercise testing to define, 715
    (*see also* Symposium on Exercise in Cardiovascular Health and Disease)
Afterload and cardiac drugs, 521
Age correlation and normal electrocardiographic limits, 271
A–H interval and atrioventricular nodal dissociation with reentry, 291
Alcohol intake, excessive, and bradycardia-dependent and tachycardia-dependent Mobitz type II atrioventricular block within bundle of His, 908
Allograft rejection and new instrument for cardiac biopsy, 264
American College of Cardiology News
  Abstracts of papers of 23rd Annual Scientific Session, American College of Cardiology, 121
    addendum to, 452
    author index to, 181
    subject index to, 185
  Calendar of continuing medical education programs, 115, 326, 455, 576, 711, 936
  Candidates certified
    by American Board of Pediatrics, Inc., Sub-Board of Pediatric Cardiology, 119
    by Subspecialty Board on Cardiovascular Disease, 116, 579
  Membership in the American College of Cardiology, 116
  New members elected, 456, 578
  1974 Board of Governors, 577
  1974–75 Committee appointments, 707
  Norms for use in peer review of selected in-hospital cardiovascular diagnoses, 697
  President's page, 454, 705
  Report to: the Executive Committee and the Board of Trustees, 114
  23rd Annual Scientific Session
    abstracts of papers of, 121
      addendum to, 452
      author index to, 181
      subject index to, 185
    welcome to, 120
Anatomy of left bundle branch in dog, 623
Aneurysm
  aortic, acute dissecting, after retrograde brachial arterial catheterization, 562
  of left atrium, congenital, 557
  ventricular, and medically uncontrollable ventricular tachyarrhythmia, 691
Aneurysmectomy for congenital left atrial aneurysm, 557
Angina pectoris
  acute myocardial infarction after exercise testing in, 813
  and aortocoronary artery saphenous vein bypass surgery, 42
  and cardiac output during exercise, 23
  and coronary atherosclerosis, coronary arteriogram in, 7
Angina pectoris
  and maximal treadmill testing, 459
  and multiple coronary arteriosystemic fistulas, 304
  and two-step vs. maximal exercise test, 797
  cardiac assist devices for, 316
  clinical history, exercise testing and atrial pacing to assess, 351
  coronary artery bypass for, 431
  indirect assessment of myocardial oxygen consumption in, 737
  intermediate syndrome, evolution of, with and without surgery, 201
  natural history of, 423
  perhexiline in, 806
  postinfarction, evolution of, with and without surgery, 201
  preinfarction, and early mortality after coronary artery bypass surgery following myocardial infarction, 483
  progressive, evolution of, with and without surgery, 201
  Q waves after coronary artery bypass surgery for, 221
  surgery vs. medical treatment for, 415
  unstable
    evolution of, with and without surgery, 201
    hemodynamic observations in, 17
Angiogram
  and chest pain in coronary artery disease, 351
  and natural history of coronary artery disease, 195
  in left atrial myxoma, 281
  in multiple coronary arteriosystemic fistulas, 304
  in pacemaker-induced cardiovascular failure, 295
Antihypertensive agents and furosemide for hypertension, 546
Aorta, coarctation of, vs. kinking of aortic arch, 286
Aortic arch
  interrupted, with ventricular septal defect and patent ductus arteriosus, surgery for, 566
  kinking of, and delayed systolic peak of femoral pulse, 286
Aortic cross-clamping and myocardial infarction after coronary artery bypass surgery, 215
Aortic nerve activity in experimental myocardial infarction, 853
Aortic valve
  leaflet, in discrete subaortic stenosis, 277
  prostheses, platelet survival in patients with, 840
Apex cardiography, quantitative, and computer study of systolic time intervals, 643
Arm-crank ergometry in coronary artery disease, 80[illegible]
Arrhythmias
  after cardiac transplantation, 604
  after coronary reperfusion, 69
  after glucagon administration, 507
  after myocardial infarction, quinidine for prevention of, 655
  after stimulation of the brain stem in monkeys, 845
  and electrophysiologic properties of procainamide, 598
  bretylium tosylate and quinidine for, 633
  future risk of, and maximal treadmill testing, 459
  induced by digitalis-diuretic therapy, serial treadmill exercise tests and, 230
  induced by exercise testing, 732
  slow calcium responses and, 689
  ventricular, portable analog computer to detect, 390
Aspirin and platelet survival in patients with prosthetic heart valves, 840
Asynergy
  and ventricular premature beats and tachycardias, 378
  ventricular, and ventriculogram in coronary artery disease, 1

Asystole during systemic hyperkalemia, 876
Atherosclerosis, coronary
and angina pectoris, coronary arteriogram in, 7
and natural history of angina pectoris, 423
factors predisposing to, and coronary collateral vessels, 12
Atrial fibrillation
and paroxysmal supraventricular tachycardia, 590
arrhythmias induced by digitalis-diuretic therapy in, and exercise testing, 230
Atrial premature contractions after cardiac transplantation, 604
Atrial septal defect
ostium secundum, and balloon mitral valve, 668
with cyanosis due to systemic venous drainage into left atrium, 674
Atrioventricular node
concealed bypasses of, in paroxysmal supraventricular tachycardia, 590
conduction through, and glucose-insulin-potassium infusion, 498
dual pathways in man, 291
in single ventricle, 95
Atrium, left, congenital aneurysm of, 557
Atropine
and reflex inhibitory effects of vagal afferents in experimental myocardial infarction, 853
cardioacceleration and myocardial blood flow in coronary artery disease induced by, 327
electrophysiologic effects of, on atrioventricular conduction, 333
Auscultation and fourth heart sound in hypertensive and normal subjects, 614
Azotemia and magnesium administration for digitalis toxicity, 225

Bacterial endocarditis and left atrial myxoma, 281
Balloon occlusion, intracoronary, for study of regional cardiac function, 49
Behavior modification for prevention of coronary heart disease in childhood, 784
Beta adrenergic blocking agents in mouse heart, 639
Bettelheim and Kauders on experimental mitral insufficiency, 904
Biochemistry of heart and exercise training, 744
Biopsy, transvenous cardiac, new instrument for, 264
Blood flow
and prognostic indexes in myocardial infarction with shock, 826
aortic, after right ventricular destruction, 254
as prognostic index in acute myocardial infarction with shock, 826
coronary
and physical training of rats, 744
in systemic hyperkalemia, 876
reserve, and critical coronary stenosis, 87
sinus, after coronary reperfusion, 69
diastolic, into pulmonary artery in carcinoid heart disease, 685
measurement in closed chest intracoronary occlusion model, 49
myocardial, and atropine-induced cardioacceleration in coronary artery disease, 327
pulmonary, and erythropheresis in cyanotic congenital heart disease, 410
velocity, measured at mitral valve of man, 541
Blood pressure
aortic, diastolic augmentation of, with nitroprusside and external counterpulsation, 819
arterial
after phentolamine in acute myocardial infarction, 37
diastolic, after nitroprusside and external counterpulsation, 819
as prognostic index in acute myocardial infarction with shock, 826
increased right atrial, in carcinoid heart disease, 685
intracardiac, and kinking of aortic arch, 286
left ventricular end-diastolic, after right ventricular destruction, 254
Blood pressure
measurement by sphygmomanometry, 107
pulmonary arterial
diastolic, in acute myocardial infarction, 357
end-diastolic, after myocardial infarction, 363
in right ventricular infarction, 209
right ventricular end-diastolic, after right ventricular destruction, 254
systolic, after physical training, 760
× heart rate × systolic ejection period in angina pectoris, 737
Book reviews
Cardiac Arrhythmias. Twenty-Fifth Hahnemann Symposium (Dreifus and Likoff, ed), 935
Cardiac Surgery (Norman, ed), 324
Cardio-Respiratory Resuscitation (Gilston and Resnekov), 323
Cerebral Vascular Diseases (8th Conference) January 5–7, 1972 (McDowell and Brennan, ed), 113
Circulatory Physiology: Cardiac Output and Its Regulation (Guyton, Jones and Coleman), 935
Echocardiography (Feigenbaum), 323
An Introduction to Respiratory Physiology (Kao), 322
Myocardial Blood Flow in Man, Methods and Significance in Coronary Artery Disease (Maseri, ed), 453
Myocardial Infarction (Corday and Swan), 322
Recent Advances in Cardiology (Hamer, ed), 322
Vectorcardiography (Benchimol), 323
Brachial artery catheterization, acute dissecting aortic aneurysm after, 562
Bradycardia-dependent block
bundle branch, after myocardial ischemia, 529
Mobitz type II atrioventricular block within bundle of His, 908
Brain stem, stimulation of, encephalogenic cardiomyopathy after, 845
Bretylium tosylate and quinidine, electrophysiologic antagonism of, 633
Bundle branch, left, bifascicular vs. fanning network, 623
Bundle branch block
after diphenylhydantoin, 493
and complete atrioventricular block in myocardial infarction, 833
and lidocaine-induced heart block, 487
complete, incomplete nature of, 583
intermittent, and paroxysmal atrioventricular block, 553
phase 4 bilateral, paroxysmal atrioventricular block related to, 553
phase 3, and paroxysmal atrioventricular block, 553
tachycardia- and bradycardia-dependent, after myocardial ischemia, 529
Bundle branch electrograms and conduction delay during systemic hyperkalemia, 876
Bundle branches in single ventricle, 95
Bundle of His, tachycardia- and bradycardia-dependent block within, 908
after myocardial ischemia, 529
Bypass grafts, occluded, after coronary artery revascularization, 431

Calcium "spikes" and depolarized myocardium, 689
Carcinoid heart disease, diastolic blood flow into pulmonary artery in, 685
Cardiac assist devices, current status of, 316
Cardiac catheterization
acute dissecting aortic aneurysm after, 562
and echocardiographic assessment of malposition of heart, 896
in pulmonary atresia and intact ventricular septum, 892
Cardiac glycosides
(*see* Digitalis and specific agents)
Cardiac hypertrophy and natural history of angina pectoris, 423

Cardiac index
after nitroprusside and external counterpulsation, 819
after phentolamine in acute myocardial infarction, 37
Cardiac innervation and arrhythmias after cardiac transplantation, 604
Cardiac output during exercise in patients with coronary artery disease, 23
Cardiac performance after physical training, 765
Cardiac specialized tissue in single ventricle, 95
Cardiac transplantation, arrhythmias after, 604
Cardiomegaly and left atrial aneurysm, 557
Cardiomyopathy
encephalogenic, after stimulation of brain stem in monkeys, 845
hypertrophic obstructive, echocardiogram in, 277
primary, and new instrument for biopsy, 264
Cardiorespiratory function and physical training, 765
Cardiovascular function, exercise testing of, 715
(*see also* Symposium on Exercise in Cardiovascular Health and Disease)
Catheter
biopsy, new, 264
Doppler flowmeter, to measure mitral valve blood flow velocity, 541
double, for evaluation of pulmonary atresia and intact ventricular septum, 892
electrode, implanted, for ventricular defibrillation, 243
system, implanted, for ventricular defibrillation, 243
Catheterization, arterial, complications after, 259
Chest pain, clinical history, exercise testing and atrial pacing to assess, 351
Chest roentgenogram
and diagnostic ultrasound to assess cardiac malposition, 896
and pulmonary arterial diastolic blood pressure in acute myocardial infarction, 357
in kinking of aortic arch, 286
in pulmonary atresia and intact ventricular septum, 892
Chordae tendineae rupture complicating systolic click-late systolic murmur syndrome, 681
Circulatory assistance
current status of, 316
in surgery for congenital left atrial aneurysm, 557
noninvasive, with nitroprusside and external counterpulsation, 819
Circumferential fiber shortening, velocity of, and left ventricular performance, 475
Click
double opening, and dysfunction of caged disc mitral valve prosthesis, 300
midsystolic, in atrial septal defect with balloon mitral valve, 668
systolic, and late systolic murmur syndrome, 681
Cohnheim, experiments on heart valves of, 268
Coincidence counting system and myocardial blood flow in coronary artery disease after atropine, 327
Computer
portable analog, to detect ventricular arrhythmias, 390
system for study of noninvasive techniques, 643
Cholesterol, serum
after physical training, 760
and patency of aortocoronary vein grafts, 679
Conduction
aberrant
and diphenylhydantoin, 493
and incomplete "complete" bundle branch block, 583
ventricular, after atropine, 333
antegrade
after atropine, 333
and verapamil in paroxysmal supraventricular tachycardia, 590
atrial, and effect of quinidine on sinus nodal reentry, 617
Conduction
atrioventricular
and electrophysiologic properties of procainamide, 598
and electrophysiology of bretylium tosylate and quinidine, 633
and phase 4 bilateral bundle branch block, 553
digoxin and, 344
electrophysiologic effects of atropine on, 333
in paroxysmal supraventricular tachycardia, 291
defects
and ischemic response in exercise electrocardiography, 721
induced by exercise testing, 732
atrioventricular, within bundle of His, 908
delay, ventricular, during systemic hyperkalemia, 876
disturbances
atrioventricular, in acute myocardial infarction, 833
in canine proximal His-Purkinje system after acute myocardial ischemia, 529
glucagon and, 507
glucose-insulin-potassium infusion and, 498
intraventricular, after diphenylhydantoin, 493
retrograde
after atropine, 333
and verapamil in paroxysmal supraventricular tachycardia, 590
system, atrioventricular, surface recording of, 384
Congenital heart disease
aneurysm of left atrium, 557
cyanotic, erythropheresis and pulmonary blood flow in polycythemia of, 410
echocardiographic assessment of malposition of heart, 896
interrupted aortic arch with ventricular septal defect and patent ductus arteriosus, surgery for, 566
kinking of aortic arch, 286
multiple coronary arteriosystemic fistulas, 304
pulmonary atresia and intact ventricular septum evaluated by double catheter technique, 892
Constitutional variables and normal electrocardiographic limits, 271
Contractility, indexes of, and ventricular dysfunction in coronary artery disease, 307
Contraction, left ventricular, and premature ventricular beats and tachycardias, 378
Contrast medium, subintimal injection of, and acute dissecting aortic aneurysm, 562
Coronary arteriogram in coronary atherosclerosis and angina pectoris, 7
Coronary arteriography
and natural history of angina pectoris, 423
and two-step vs. maximal exercise test, 797
Coronary artery
multiple fistulas of, 304
reperfusion after coronary occlusion, 69
stenosis of, critical, and coronary flow reserve, 87
Coronary artery disease
(*see also* Symposium on the Effects of Surgical Treatment on the Natural History of Acquired Heart Disease and Symposium on Exercise in Cardiovascular Health and Disease)
analog computer to detect ventricular arrhythmias in, 390
and angina pectoris, aortocoronary bypass vs. medical treatment for, 415
and aortocoronary saphenous vein bypass surgery, 42
and disturbances of cardiac rhythm and conduction induced by exercise testing, 732
and evolution of unstable angina pectoris, 201
and long-term physiologic adaptations to exercise, 765
and natural history of angina pectoris, 423
and preinfarction ill health, 446
and unstable angina pectoris, 17

Coronary artery disease
arm-crank ergometry in, 801
atropine-induced cardioacceleration and myocardial blood flow in, 327
biplane and single plane ventriculogram in, 1
cardiac output during exercise in, 23
clinical history, exercise testing and atrial pacing to assess chest pain in, 351
early mortality after bypass surgery for, 483
isometric vs. dynamic exercise testing in, 791
medical screening for exercise conditioning programs in, 752
methods of exercise testing in, 715
myocardial infarction after coronary artery bypass surgery for, 215, 221
natural history of, angiogram and, 195
perhexiline in, 806
posterior wall velocity and left ventricular performance in, 475
progressive vs. stable, with angina pectoris, 7
Q waves after coronary artery bypass surgery for, 221
submaximal isometric handgrip exercise in, 30
two-step vs. maximal exercise test in, 797
ventricular dysfunction in, 307
Coronary care unit
activity program in, 776
analog computer to detect ventricular arrhythmias in, 390
Coronary collateral circulation
and factors predisposing to atherosclerosis, 12
and natural history of coronary artery disease, 195
Coronary collateral vessels in progressive and stable coronary artery disease, 7
Coronary heart disease as a pediatric problem, 784
(*see also* Coronary artery disease)
Coronary insufficiency, isometric vs. dynamic exercise testing in diagnosis of, 791
Coronary occlusion
and cardiac drugs, 521
and effects of reperfusion on infarct size, 82
and hemodynamics after reperfusion, 69
and nitroglycerin in acute myocardial infarction, 513
closed chest model of, 49
hemodynamics after, 60
nitroglycerin-induced reduction of spontaneous ventricular fibrillation during, 517
Coronary risk factors
and coronary collateral circulation, 12
effects of physical training on, 760
Coumadin and platelet survival in patients with prosthetic heart valves, 840
Counterpulsation, external, and nitroprusside in myocardial infarction, 819
Creatine phosphokinase
after injection of gallium-67 in acute myocardial infarction, 861
and myocardial infarction after coronary artery bypass surgery, 215
isoenzyme activity, quantification of, 650
Cuff-bladder assembly for sphygmomanometry, 107
Cyanosis
due to systemic venous drainage into left atrium in atrial septal defect, 674
in congenital heart disease, erythropheresis and pulmonary blood flow in, 410
Cystic medial degeneration and acute dissecting aortic aneurysm, 562

Death, sudden
and analog computer to detect ventricular arrhythmias, 390
ill health preceding, 446
prospective study of antecedents of, 459
Defibrillation, ventricular, with implanted and partially implanted electrode systems, 243
Depolarization
adrenaline-induced, role of calcium in, 689
atrial premature, and digoxin, 344
frequency-related transient, and escape rhythm, 248
phase 4, in bradycardia-dependent block, 908
spontaneous diastolic, and paroxysmal atrioventricular block, 553
Dextrocardia, diagnostic ultrasound for, 896
Diabetes and large dose furosemide therapy for hypertension, 546
Diet for prevention of coronary heart disease in childhood, 784
Digitalis
(*see also* Ouabain)
and atrioventricular conduction patterns in man, 344
serum, and serum magnesium levels, 225
therapy in atrial fibrillation, exercise testing and, 230
toxicity
and serum magnesium levels, 225
ventricular escape rhythms induced by, 248
Digitoxin toxicity, and serum magnesium levels, 225
Digoxin
and atrioventricular conduction patterns in man, 344
and isometric handgrip exercise in coronary artery disease, 30
Diphenylhydantoin and intraventricular conduction of aberrant beats, 493
Diuretic therapy
in atrial fibrillation, exercise testing and, 230
vs. furosemide for hypertension, 546
Doppler flowmeter
and complications of arterial catheterization, 259
catheter to measure mitral valve blood flow velocity, 541
Double product to assess angina pectoris, 737
Drug overdose, prognostic indexes in, 826
Ductus arteriosus, patent, with ventricular septal defect and interrupted aortic arch, surgery for, 566
Dyspnea on effort, preceding myocardial infarction, 446

Echocardiogram
and indexes of left ventricular performance, 475
and left ventricular internal dimensions after myocardial infarction, 363
in dextrotransposition of great vessels, 321
in discrete subaortic stenosis, 277
in left atrial myxoma, 281
in muscular subaortic stenosis, 277
in primary pulmonary hypertension, 438
to assess malposition of heart, 896
Ectopic activity and ouabain toxicity, 248
Education
and individual exercise prescription, 757
and physical fitness programs for adults, 787
in childhood, to reduce risk factors for coronary artery disease, 784
Eisenmenger syndrome, late results of surgery for, 403
Ejection fraction
after acute myocardial infarction, 370
after surgery and medical treatment for angina pectoris, 415
and ventricular dysfunction in coronary artery disease, 307
and ventriculogram in coronary artery disease, 1
Electrical stability and nitroglycerin in acute myocardial infarction, 513
Electrocardiogram
after coronary artery bypass surgery for angina pectoris, 221

Electrocardiogram
after stimulation of the brain stem in monkeys, 845
after surgery and medical treatment for angina pectoris, 415
and atrioventricular conduction after digoxin, 344
and medical screening of patients for exercise conditioning programs, 752
and myocardial infarction after coronary artery bypass surgery, 215
and natural history of angina pectoris, 423
during complete atrioventricular block in acute inferior myocardial infarction, 833
during two-step and maximal exercise test, 797
Frank lead, and differentiation of right ventricular hypertrophy and posterior myocardial infarction, 608
in acute pericarditis, 470
in atrial septal defect with balloon mitral valve, 668
intracoronary, and closed chest intracoronary occlusion model, 49
normal limits of, principles in establishing, 271
Electrocardiography, exercise
and risk of future cardiac events, 459
recognition of ischemic response in, 721

INSTRUCTIONS FOR AUTHORS

The editors and publishers of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- **Address manuscript** to Simon Dack, MD, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- **Submit two copies** of all elements of the article: text, references, legends, tables and figures.
- **Arrange the paper** in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- **Number all pages** in above sequence, beginning with title page as 1, abstract as 2, etc.
- **Type all matter:** (1) on 8½ × 11 opaque white bond paper; (2) in duplicate; (3) on **one side** of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- **Number title page** as page 1.
- **Include first names,** degrees and, where applicable, FACC for all authors.
- **Insert at bottom:** name and address of institution from which work originated plus information about grants.
- **Add at bottom** the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- **Limit words as follows:** 100 to 250 words for major articles; 50 to 100 words for case reports.
- **Add at end of abstract:** an alphabetical list of 2 to 6 key words and subjects for indexing.

THE TEXT

- **Number pages** in sequence after abstract.
- **Type in duplicate;** double-space.
- **Do not use abbreviations** such as SVC, WPW: write out; superior vena cava, Wolff-Parkinson-White.

Abbreviate measurements (mm, kcal and the like) as recommended in the Style Manual for Biological Journals, American Institute of Biological Sciences, 3900 Wisconsin Avenue, N.W., Washington, D. C.

- **Cite in numerical** order every reference, figure and table. (Order of mention in text **determines the number** given to each.)
- **Place acknowledgments** at end of text, before references.

THE REFERENCES

- **Type in duplicate;** double-space.
- **Place immediately** after text, and number pages in sequence after text page numbers.
- **Number the references** in order in which they are mentioned in text.
- **Follow the general** arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- **Start at top** of new page.
- **Type in duplicate;** double-space.
- **Number pages** in sequence after last page of references.
- **Identify at** the end of each legend and **in alphabetical order** all abbreviations in the figure described.

THE TABLES

- **Start each** table at top of new page.
- **Type in duplicate;** double-space.
- **Number pages** in sequence after last page of legends.
- **Give each table** a number (in roman numerals: Table I, II, etc.) and a title. Number the tables in order in which they are mentioned in the text.
- **Provide a footnote** to each table—identifying **in alphabetical order** all abbreviations used.

THE FIGURES

- **Submit 2 glossy prints** (not originals) of each photo and drawing.

Please note that art work of published articles will not be returned.

- **Use black ink** for all charts (line drawings). Make decimals, broken lines, etc. strong enough for reproduction.
- **Use arrows** to designate special features.
- **Crop photomicrographs** to show only essential field.
- **Identify figures** on back by number and author's name.
- **Number figures** in order in which they are mentioned in the text.
- **Indicate top** of each figure.
- **Submit written permission** from publisher and author to reproduce any previously published figures.
- **Limit figures** to number necessary for clarity. The publisher allows a limited sum toward reproduction.

Examples of Styles of References

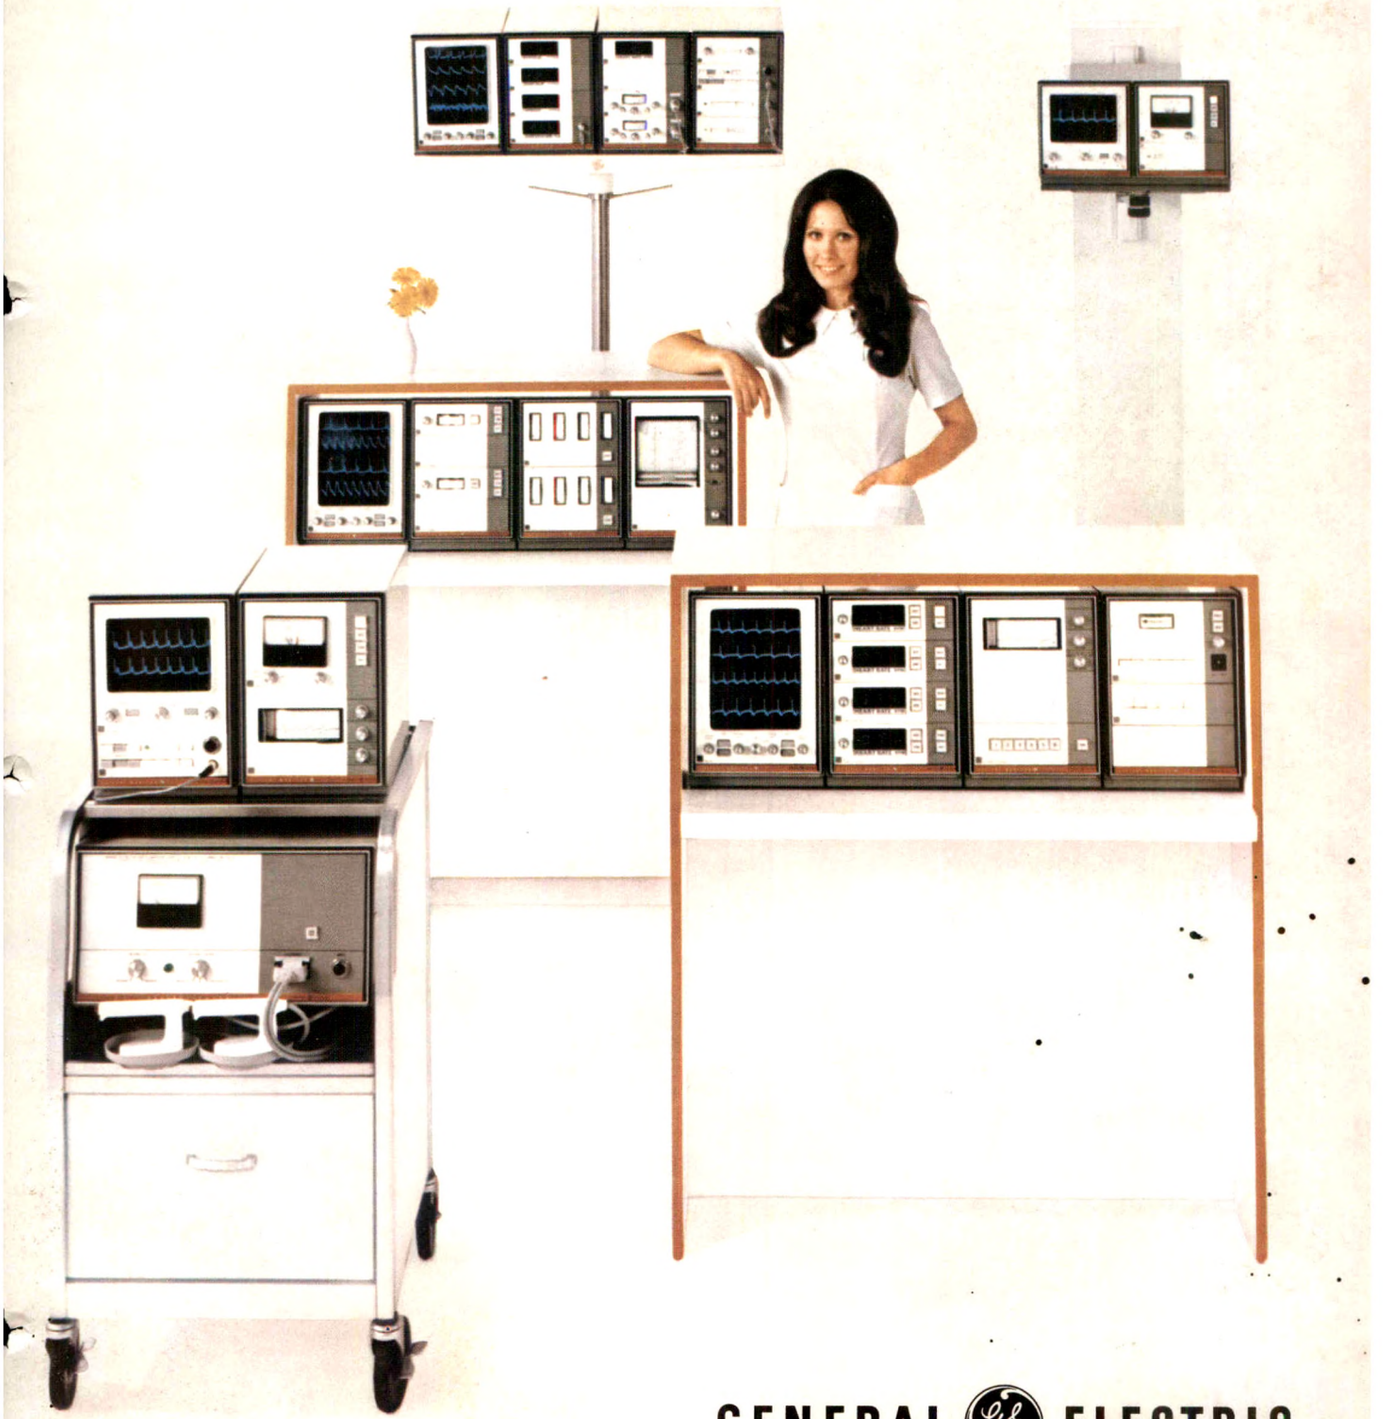
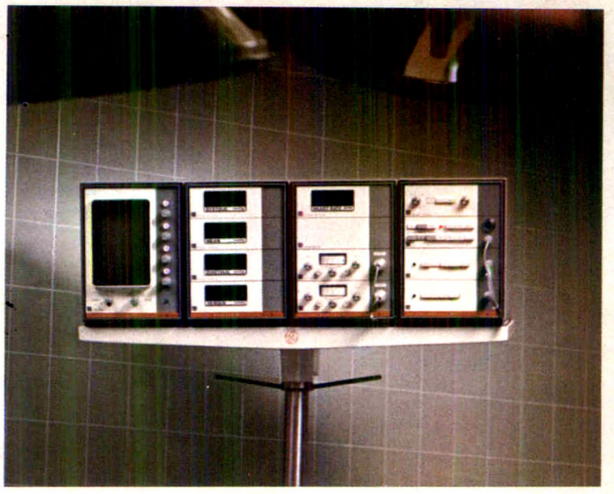
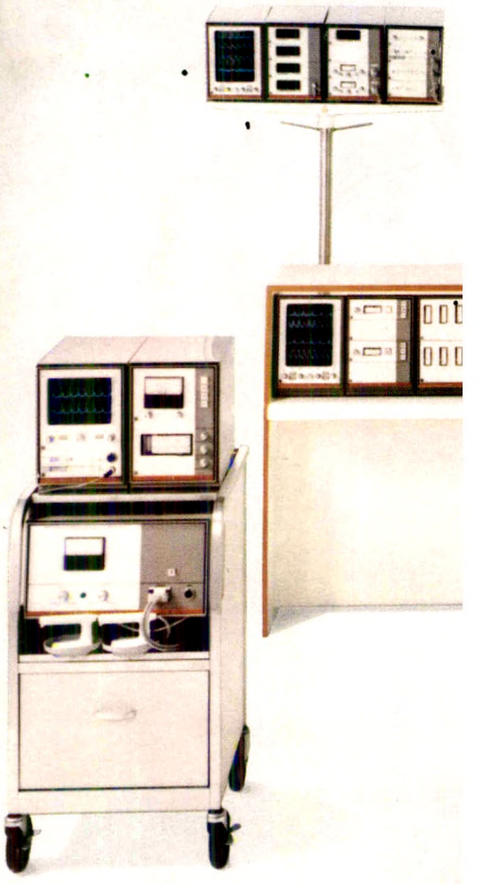
(Author: all book references should have specific page numbers)

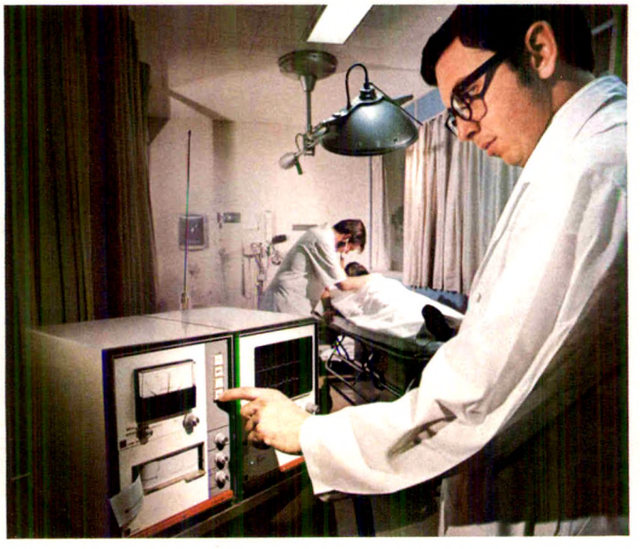
Ubiquitous.



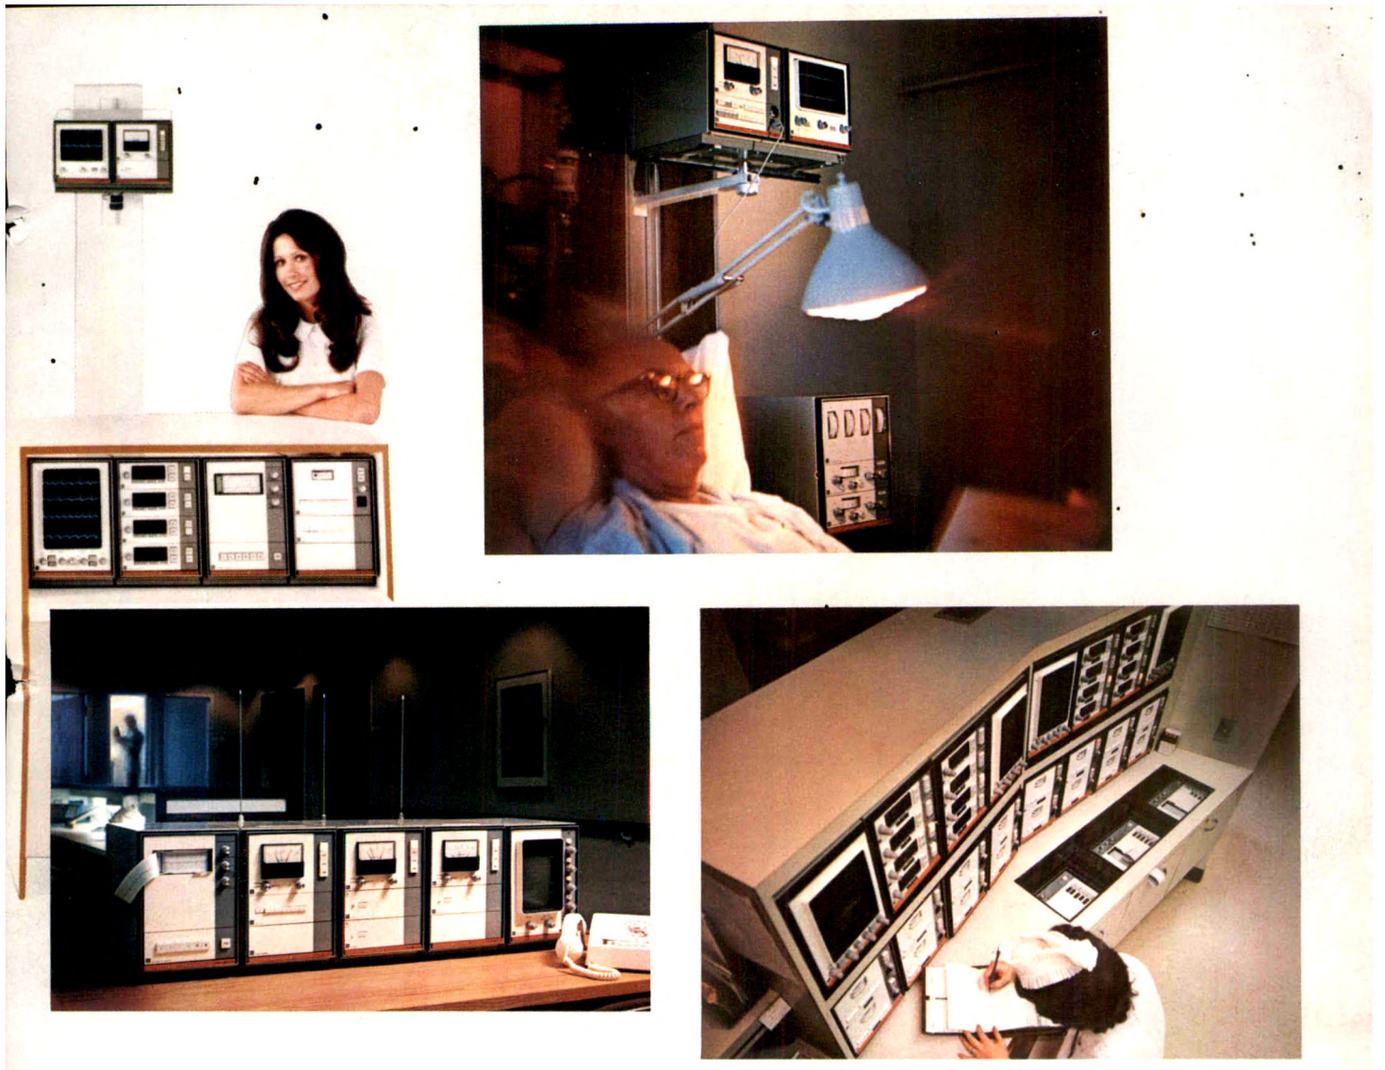
GENERAL ELECTRIC







GE Patient Monitoring Systems respond to multiple-location demands.



Ubiquitous, the quality of being present everywhere, aptly describes General Electric monitoring systems. Modular design and mobility offer ease of positioning and flexible use at any location.

In critical care areas where expansion is anticipated, GE provides both basic and optimum ICU/CCU configurations. Modules can be combined to meet growth requirements. The choice of monitored parameters is also flexible. These can include ECG, EEG, heart rate, blood pressure, respiration, temperature and pulse. An arrhythmia monitor and a D-C defibrillator complete the system.

A mobile system best exemplifies the ubiquity of GE monitoring capability. This cart-mounted unit can serve in any critical care or emergency situation where mobility and monitoring flexibility are essential. The system supplements any fixed monitoring installation, and can be used in outpatient or overload areas.

In the O.R., GE's surgical monitoring system positions all modules atop a mobile 5-foot stand, with all power cables and signal leads contained within the single-support column, exiting at the base. The result is less clutter, more elbow room for the O.R. team, and no monitors too near the sterile field. For added safety, ECG, EEG and pulse amplifiers are optically coupled to preclude shock hazards.

When the patient is ambulatory, GE Telemetry can monitor and transmit ECG data to the nurse station from remote locations. This expanded monitoring capability enables you to evaluate heart activity during the still-crucial period prior to patient release.

The tiny transmitter accepts 2 GE Daisy or pre-jelled Daisy electrodes for high signal fidelity. It can transmit continuously for 7 days or more on a miniature battery.

Learn how GE's ubiquitous monitoring systems can maximize the efficiency of your monitoring equipment needs. See your GE representative.

GENERAL ELECTRIC

GE leasing and service plans are ubiquitous, too.

GE leasing plans can conserve capital, freeing it for investment in other ways. Maxiservice®, the true-lease and maintenance plan, incorporates emergency service, including all parts and labor. Even insurance. At a budgeted monthly fee.

And you can guard against obsolescence by upgrading to new equipment when you desire. Equipment such as the Patient Data System, a third generation monitoring concept which integrates a computer as an extension of basic processing capability. But unlike computer-dependent systems, PDS allows you to derive patient information without the computer. The result is a flexible system to meet immediate monitoring requirements, and extremely sophisticated long-term needs.

A word about the monitoring service teams. They're part of a nationwide group that receives intensive training on monitoring equipment exclusively. These men participate in on-going training, both in the field and periodically at GE's Medical Systems Institute.

A full range of leasing and service plans. The top service group in the industry. It's the kind of total commitment no other monitoring systems supplier can rival.

ACCEL™

AMERICAN COLLEGE OF CARDIOLOGY EXTENDED LEARNING

NOW YOU CAN PARTICIPATE IN A MONTHLY AUDIOTAPE PROGRAM

EXCLUSIVE TO THE FIELD OF CARDIOLOGY

This multimedia (tapes, slides, printed booklet) audio tape program includes 60 minutes of clinically oriented information on the art of diagnosis and treatment of cardiovascular disease to its subscribers each month. The audio cassette tapes include recorded panel discussions interviews with noted authorities and self-assessment quizzes. In addition, 35 mm slides and a monthly personal continuing education notebook are supplied as a part of this professional service.

Join the more than 4,500 subscribers who are listening each month.

MONTREAL, P.Q. CANADA ☐ MUNICH, GERMANY

You expect a lot from a pacemaker with a 36 month full replacement warranty.

And you get a lot from the IDP-54:

An implantable R-wave-inhibited pacemaker for intracardial and myocardial stimulation for a low, constant stimulation threshold.*

Low energy consuming circuitry and the new Mallory cell producing up to 4 to 5 years operating life.

36 month full replacement warranty.

Suitability for initial implant or implantation in patients with existing implanted electrode systems.

* The implantation of an R-wave-inhibited pacemaker has been well proven in the following cases: intermittent AV block with predominant sinus rhythm, recurrent bradycardia and second implantation to replace a fixed rate pacemaker with virtual return to sinus rhythm.

Get to know Biotronik, the pacemakers known for quality.

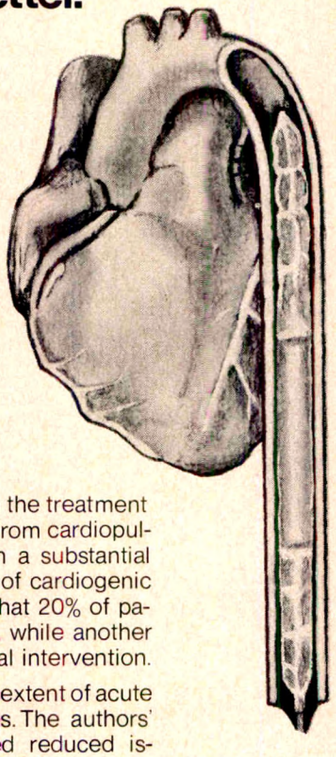
"a life-saving measure in a substantial minority of patients"[1]

The Avco Intra-Aortic Balloon Pump* ...and the Sooner, the Better.

The rationale of intra-aortic balloon pump (IABP) therapy in low-cardiac output conditions is widely accepted. By lowering pressure in the proximal aorta at the beginning of systole, myocardial work load is lessened. Also, by augmenting pressure during early diastole, pumping improves coronary perfusion and can open dormant collaterals. Thus a better balance between myocardial oxygen demand and consumption is obtained.



Documented effectiveness

The IABP's effectiveness is clinically proven in the treatment of cardiogenic shock and in weaning patients from cardiopulmonary bypass. It is a "lifesaving measure in a substantial minority of patients who would otherwise die of cardiogenic shock."[1] Braunwald and Maroko[2] estimate that 20% of patients who would otherwise die can be saved, while another 20% can be stabilized for diagnosis and surgical intervention.

IABP "significantly reduced the magnitude and extent of acute myocardial ischemic injury"[3] in animal studies. The authors' preliminary clinical results also demonstrated reduced ischemia as well as hemodynamic improvement.

Time a critical factor

Hemodynamic criteria to determine if a patient who seems to be going into cardiogenic shock is responding to treatment have been developed by Leinbach.[4] These criteria are a major contribution to the effective application of IABP treatment since *early use* of the system greatly increases the chances of success. Buckley and associates[5] used the IABP in 27 heart-surgery patients who went into shock upon termination of cardiopulmonary bypass. Eighteen survived; 13 are long term survivors. Best results occurred with initiation of IABP therapy early in the postoperative period.

*Developed by Avco Corporation and manufactured for Roche Medical Electronics Division.

The IABP versus drugs

Dunkman and others[6] have concluded that "catecholamines may actually increase ventricular dysfunction and necrosis" whereas the IABP's enhancement of coronary perfusion and reduction of oxygen-consuming work in the left ventricle can save patients if applied before about 40% of the left ventricle is irretrievably damaged. Moreover, IABP permits safe use of drugs if needed.

AVCO, the most experienced system

The internal counterpulsation system most widely used clinically is the Avco IABP. There are some very practical reasons for this dominance.

Patented 3-chamber balloon design prevents end occlusion.

QRS triggered synchronization with normal and abnormal rhythms.

Automatic reset for changes in interval or loss of R wave.

Safety engineering with fail-safe venting, self-initiated trouble identification, and emergency compressor with independent power supply.

Nationwide on-site service.

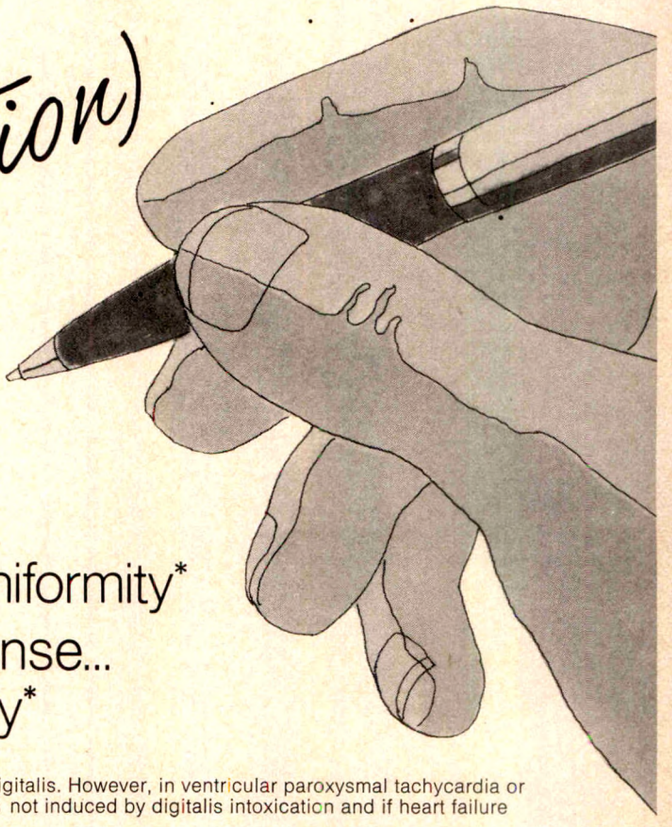
Lanoxin

[digoxin]

(no substitution)



write it

precision quality control...

- assured tablet content uniformity*

predictable patient response...

- proven biologic availability*

Contraindications: There are no absolute contraindications to digitalis. However, in ventricular paroxysmal tachycardia or ventricular fibrillation, it should be used *only* in refractory cases not induced by digitalis intoxication and if heart failure has developed.

Precautions: If the patient has been given digoxin during the previous week or any other less rapidly excreted drug of the digitalis group during the previous two weeks, the dose of Lanoxin brand Digoxin must be reduced accordingly. Because of impaired renal function and excretion in elderly patients, they frequently require lower than recommended doses.

Potassium loss in patients sensitizes the heart to digitalis intoxication even with recommended doses. The diuretic agents as well as electrolyte manipulations by the physician are major causes of potassium depletion in cardiac patients. Under these conditions, it may be necessary to reduce the usual dosages of Lanoxin brand Digoxin during digitalization and maintenance.

Digoxin is usually ineffective in cases of cardiac failure due to mechanical causes which are independent of myocardial diseases, e.g., cardiac tamponade, or to disorders not primarily of cardiac origin, as severe anemia. Despite a variable or poor response to digoxin in the presence of active rheumatic carditis, the development of cardiac failure is an indication for its use.

Effects of Overdosage and Treatment: The symptoms of overdosage with digoxin are quite similar to those occurring with other digitalis preparations. The most common toxic manifestations are anorexia, nausea, vomiting and various cardiac arrhythmias, including ventricular extrasystoles and paroxysmal supraventricular tachycardia or fibrillation with A-V block. In general, the gastrointestinal manifestations of toxicity with digoxin precede the cardiac arrhythmias occurring from overdosage. Furthermore, because of the rapid dissipation of digoxin, manifestations of toxicity are of short duration, usually lasting from a few hours to one or two days.

If necessary, potassium chloride may be administered as an intravenous infusion containing (adult dosage) 40 milliequivalents in 500 cc. of 5% dextrose in water, given over the course of 1 hour and repeated, if required, until a total of 120 milliequivalents have been given (1 mEq. KCl = 74.5 mg.). Electrocardiographic monitoring should be conducted and the infusion halted immediately upon the appearance of peaking of the T-waves. For children, the intravenous infusion dosage of potassium chloride would be 5 to 10 milliequivalents in 100 cc. of 5% dextrose in water given over the course of 1 hour, repeated if required, to a total of 15 to 30 milliequivalents. For more serious intoxication with abnormal cardiac rhythms, potassium chloride may be given orally in divided doses totalling 4 to 6 grams per day (adults) or 1 to 2 grams (children) provided renal failure is not present.

LANOXIN® digoxin TABLETS. **0.125 mg.** (yellow) in bottles of 100 and 1,000. **0.25 mg.** (white) scored, in bottles of 100, 500, 1,000 and 5,000; also Unit Dose Pack, strips of 10 tablets, 10 boxes of 100 tablets (1,000). **0.5 mg.** (green) scored, in bottles of 100 and 1,000.

Lanoxin® digoxin

The newest Ekoline 20A® features multi-parameter capability.

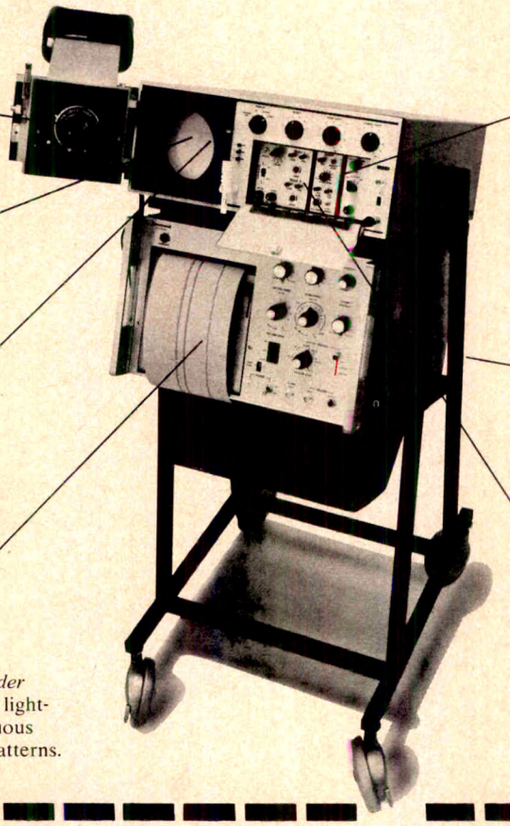
Two new modules give the Smith Kline Instruments Ekoline 20A® an unmatched multi-trace capability. The Isolated Sweep/EKG Module and the Multi-Parameter Amplifier Module enable the E20A Ultrasonoscope to produce traces for ultrasound, EKG, phono and carotid pulse or apex. Combine this with the Fiber-optic Recorder and the result is high quality, grey scale strip chart recordings of pertinent information—at a surprisingly low cost.

1. *New Oscilloscope Camera* features built-in electronic shutter release, uses high-speed 'Polaroid' film.

2. *New High-Resolution Oscilloscope* is standard on all 'Ekoline 20A' instruments, gives outstanding display of all echo patterns.

3. *New Long-Persistence Oscilloscope* available as optional equipment, uses P7 phosphor to provide best possible display of M-mode echo patterns.

4. *New Fiber-Optic Line-Scan Recorder* utilizes fiber-optic CRT to expose light-sensitive paper, producing continuous "strip-chart" recordings of echo patterns.



5. *New Isolated Sweep/EKG System* Converts A-Mode echo display from a moving organ into M-Mode display. Features isolated, linear, and movable EKG.

6. *New Equipment Cart* conveniently houses 'Ekoline 20A' and Recorder. Permits complete system to be readily moved to any location throughout the hospital.

7. *New Multi-Parameter Amplifier Module* provides the capability for echo, EKG, phono and carotid pulse or apex traces.

REQUEST FOR ADDITIONAL INFORMATION

Please:

☐ Have representative call me to arrange a demonstration.

☐ Send detailed literature.

Circulation

VOL. XLIX JUNE, 1974 NUMBER 6

CONTENTS

ORIGINAL ARTICLES:

Ineffectiveness of Glucose, Potassium, and Insulin Infusion During Pacing Stress in Chronic Ischemic Heart Disease. Michael Lesch, Louis E. Teichholz, J. Stuart Soeldner and Richard Gorlin

Effect of Inotropic Agents on the Localized Dyskinesis of Actuely Ischemic Myocardium: An Experimental Ultrasound Study. Richard E. Kerber, Francois M. Abboud, Melvin L. Marcus and Dwain L. Eckberg

Serum, Atrial, and Urinary Digoxin During Cardiopulmonary Bypass in Children. Richard W. Krasula, Alois R. Hastreiter, Sidney Levitsky, Ruth Yanagi, and Lester F. Soyka

The Effects of Digitalis Glycosides on the Ventricular Fibrillation Threshold in Innervated and Denervated Canine Hearts. Anthony George, Joseph F. Spear and E. Neil Moore

Comparison of Serum Digoxin Level Measurement with Acetyl Strophanthidin Tolerance Testing. Michael D. Klein, Bernard Lown, Isaac Barr, Frans Hagemeijer, Henry Garrison and Paul Axelrod

Augmentation of Left Ventricular Contraction Pattern in Coronary Artery Disease by an Inotropic Catecholamine: The Epinephrine Ventriculogram. Howard R. Horn, Louis B. Teichholz, Peter F. Cohn, Michael V. Herman and Richard Gorlin

The Inotropic Effects of the Calcium Ionophore X-537A in the Anesthetized Dog. Norberto T. de Guzman and Berton C. Pressman

Propranolol in the Treatment of Acute Myocardial Infarction: Effect on Myocardial Oxygenation and Hemodynamics. Hiltrud S. Mueller, Stephen M. Ayres, Anna Religa, and Robert G. Evans

Comparison of Isovolumic and Ejection Phase Indices of Myocardial Performance in Man. Kirk L. Peterson, David Skloven, Philip Ludbrook, John B. Uther and John Ross, Jr.

Pre- and Postoperative Rest and Exercise Hemodynamics in Children with Pulmonary Stenosis. Frederic M. Stone, F. Blanton Bessinger, Jr., Russell V. Lucas, Jr. and James H. Moller

EDITORIALS:

On the Critical Lower Level of Cerebral Blood Flow in Man with Particular Reference to Carotid Surgery. Gudrun Boysen, Hans Christian Engell, Giuseppe R. Pistolese, Paolo Fiorani, Alessandro Agnoli and Niels A. Lassen

On Reading Electrocardiograms. Ernest Craige

The Influence of Heart Rate and Age on the Systolic and Diastolic Time Intervals in Children. S. Spitaels, R. Arbogast, J. C. Fouron and A. Davignon

Biventricular Cineangiography in the Evaluation of Patients with Asymmetric Septal Hypertrophy. David R. Redwood, James L. Scherer and Stephen E. Epstein

Selective Coronary Arteriography in Young Men: A Follow-Up of 449 Patients. Juan S. Lim, William L. Proudfit and F. Mason Sones, Jr.

Necropsy Studies in Myocardial Infarction with Minimal or No Coronary Luminal Reduction Due to Atherosclerosis. R. S. Eliot, G. Baroldi and A. Leone

Antecedents of Cardiovascular Disease in Six Solomon Islands Societies. Lot B. Page, Albert Damon and Robert C. Moellering, Jr.

A Sector Scanner for Real Time Two-Dimensional Echocardiography. James M. Griffith and Walter L. Henry

Echocardiographic Features of Congestive Cardiomyopathy Compared with Normal Subjects and Patients with Coronary Artery Disease. Betty C. Corya, Harvey Feigenbaum, Susan Rasmussen and Mary J. Black

Vital Capacity and Congestive Heart Failure: The Framingham Study. W. B. Kannel, J. M. Seidman, W. Fercho and W. P. Castelli

Thrombotic Calcific Mitral Stenosis: Morphology of the Calcific Mitral Valve. Charles F. Wooley, Nobuhisa Baba, James W. Kilman and Joseph M. Ryan

Coarctation of the Aorta with Congenital Mitral Regurgitation. Michael D. Freed, John F. Keane, Richard Van Praagh, Aldo R. Castaneda, William F. Bernhard and Alexander S. Nadas

The Effect of Isometric Exercise on the Left Ventricular Volume in Man. Miltiadis A. Stefadouros, William Grossman, Mahfouz El Shahawy and A. Calhoun Witham

Coronary Perfusion Versus Cold Ischemic Arrest During Aortic Valve Surgery: A Randomized Study. Ralph N. Sapsford, Eugene H. Blackstone, John W. Kirklin, Robert B. Karp, Nicholas T. Kouchoukos, Albert D. Pacifico, Charles B. Roe and Edwin R. Bradley

Unusual Properties of Accessory Pathways. Douglas P. Zipes, Robert L. DeJoseph and Donald A. Rothbaum

The Missing Waveform Information in the Orthogonal Electrocardiogram (Frank Leads): III. Computer Diagnosis of Angina Pectoris From "Maximal" QRS Surface Waveform Information At Rest. F. Kornreich, P. Block and D. Brismee

The Missing Waveform Information in the Orthogonal Electrocardiogram (Frank Leads): IV. Computer Diagnosis of Biventricular Hypertrophy From "Maximal" Surface Waveform Information. F. Kornreich, P. Block and D. Brismee

Electrophysiological Delineation of the Specialized A-V Conduction System in Patients with Congenital Heart Disease: II. Delineation of the Distal His Bundle and the Right Bundle Branch. Ehud Krongrad, James R. Malm, Fredreick O. Bowman, Jr., Brian F. Hoffman and Albert L. Waldo

CLINICOPATHOLOGIC CORRELATIONS:

De Subitaneis Mortibus. VI. Two Young Soldiers. Thomas N. James, Richard S. Armstrong, Jay Silverman and Thomas K. Marshall

RADIOLOGY:

The Significance of Coronary Calcification Detected by Fluoroscopy: A Report of 360 Patients. Alan G. Bartel, James T. Chen, Robert H. Peter, Victor S. Behar, Yihong Kong and Richard G. Lester

CASE REPORTS:

Augmentation of Electrical Alternans with Lowering of the Heart Rate in Massive Pericardial Effusion: Report of a Case. Dennis V. Cokkinos, Constantine Kelesides, John Siaterlis and Evangelos Halimos

Echocardiographic Detection of Supravalvular Aortic Stenosis. Bruce W. Usher, Dudley Goulden and Joseph P. Murgo

BOOK REVIEWS

LETTERS TO THE EDITOR:

Prognostic Value of ST-Elevation. John E. Madias, William B. Hood, Jr.

Thrombosis and Myocardial Infraction: The Relationship of Fibrin Crosslinking to Postmortem Findings. Earl W. Ferguson

The Fourth Heart Sound. David H. Spodick; Morton E. Tavel

Echocardiography in Normal Newborns. Raymond Gramiak; Arthur D. Hagan, David J. Sahn and William F. Friedman

Exercise Testing in CAD. Robert H. Bilbro; Michael H. Kelemen

Mitral Valve Prolapse. Robert M. Jeresaty, N. Ranganathan, M. D. Silver and E. D. Wigle

Protective Effect of Vagal Stimulation after Experimental Acute Myocardial Infarction. Werner Meesmann, Klaus Stephen

CONTENTS: VOLUME 33

JANUARY 1974

CLINICAL STUDIES

1 **Comparison of Biplane and Single Plane Left Ventriculograms in Patients with Coronary Artery Disease.** Peter F. Cohn, Richard Gorlin, Douglass F. Adams, Robert A. Chahine, Pantel S. Vokonas and Michael V. Herman

7 **Devolutionary Pattern of Coronary Atherosclerosis in Patients with Angina Pectoris. Coronary Arteriographic Studies.** Demetrios Kimbiris, Peter Lavine, Hans Van Den Broek, Moosa Najmi and William Likoff

12 **Effects of Factors Predisposing to Atherosclerosis on Formation of Coronary Collateral Vessels.** Robert A. Heinle, Robert I. Levy and Richard Gorlin

17 **Hemodynamic Observations in Patients with Unstable Angina Pectoris.** David S. Cannom, Donald C. Harrison and John S. Schroeder

23 **Maximal Cardiac Output During Exercise in Patients with Coronary Artery Disease.** John R. McDonough, Ruth A. Danielson, Robert E. Wills and Donald L. Vine

30 **Effects of Submaximal Isometric Handgrip on Left Ventricular Size and Wall Motion.** Philip Ludbrook, Joel S. Karliner and Robert A. O'Rourke

37 **Enhanced Left Ventricular Performance with Phentolamine in Acute Myocardial Infarction.** Paul Walinsky, Kanu Chatterjee, James Forrester, William W. Parmley and H. J. C. Swan

42 **Results of Aortocoronary Artery Saphenous Vein Bypass Surgery for Ischemic Heart Disease.** Moosa Najmi, Kiyoji Ushiyama, Gumersindo Blanco, Alberto Adam and Bernard L. Segal

EXPERIMENTAL STUDIES

49 **Closed Chest Model of Intracoronary Occlusion for Study of Regional Cardiac Function.** Eliot Corday, Tzu-Wang Lang, Samuel Meerbaum, Herbert Gold, Shigeru Hirose, Steven Rubins and Marina Dalmastro

60 **Progressive Alterations of Cardiac Hemodynamic and Regional Metabolic Function After Acute Coronary Occlusion.** Samuel Meerbaum, Tzu-Wang Lang, Eliot Corday, Steven Rubins, Shigeru Hirose, Costantino Costantini, Herbert Gold and Marina Dalmastro

69 **Consequences of Reperfusion After Coronary Occlusion. Effects on Hemodynamic and Regional Myocardial Metabolic Function.** Tzu-Wang Lang, Eliot Corday, Herbert Gold, Samuel Meerbaum, Steven Rubins, Costantino Costantini, Shigeru Hirose, Jules Osher and Victor Rosen

82 **Deleterious Effects Due to Hemorrhage After Myocardial Reperfusion.** Gerald F. Bresnahan, Robert Roberts, William E. Shell, John Ross, Jr. and Burton E. Sobel

87 **Physiologic Basis for Assessing Critical Coronary Stenosis. Instantaneous Flow Response and Regional Distribution During Coronary Hyperemia as Measures of Coronary Flow Reserve.** K. Lance Gould, Kirk Lipscomb and Glen W. Hamilton

PEDIATRIC CARDIOLOGY

95 **Cardiac Specialized Tissue in Hearts with an Apparently Single Ventricular Chamber (Double Inlet Left Ventricle).** Robert H. Anderson, Robert Arnold, Mohinder K. Thapar, Richard S. Jones and David I. Hamilton

EDITORIALS

107 **Updating Sphygmomanometry.** Leonard Steinfeld, Harold Alexander and Myron L. Cohen

SPECIAL DEPARTMENTS

111 **Reviews in Cardiology**

185 **Subject Index: Abstracts**

CONTENTS: VOLUME 33

FEBRUARY 1974

CLINICAL STUDIES

195 **Natural History of Severe Proximal Coronary Artery Disease as Documented by Coronary Cineangiography.** Joel S. Webster, Carl Moberg and Gustavo Rincon

201 **Unstable Angina—Prospective and Randomized Study of Its Evolution, With and Without Surgery. Preliminary Report.** Carlos A. Bertolasi, Jorge E. Trongé, César A. Carreno, Jorge Jalon and Marcelo Ruda Vega

209 **Right Ventricular Infarction. Clinical and Hemodynamic Features.** Jay N. Cohn, Nabil H. Guiha, Martin I. Broder and Constantinos J. Limas

215 **Electrocardiographic and Serum Enzyme Changes of Myocardial Infarction After Coronary Artery Bypass Surgery.** Malcolm R. Rose, Ephraim Glassman, O. Wayne Isom and Frank C. Spencer

221 **New Q Waves After Coronary Artery Bypass Surgery for Angina Pectoris.** Jaime Espinoza, Janet Lipski, Robert Litwak, Ephraim Donoso and Simon Dack

225 **Correlation of Serum Magnesium Levels and Cardiac Digitalis Intoxication.** George A. Beller, William B. Hood, Jr., Thomas W. Smith, Walter H. Abelmann and Warren E. C. Wacker

230 **Influence of Exercise on Arrhythmias Induced by Digitalis-Diuretic Therapy in Patients with Atrial Fibrillation.** Alden S. Gooch, Gangaiah Natarajan and Harry Goldberg

EXPERIMENTAL STUDIES

238 **Effect of Procainamide on Fibrillation Threshold of Normal and Ischemic Ventricles.** Myung S. Yoon, Jaok Han, Brij G. Goel and Paula Creamer

243 **Ventricular Defibrillation in the Dog Using Implanted and Partially Implanted Electrode Systems.** John C. Schuder, Harry Stoeckle, Jerry H. Gold, Joe A. West and James A. Holland

248 **Accelerated Cardiac Escape Rhythms Caused by Ouabain Intoxication.** Douglas P. Zipes, Emanuel Arbel, Russel F. Knope and Gordon K. Moe

254 **Predominant Right Ventricular Dysfunction After Right Ventricular Destruction in the Dog.** Nabil H. Guiha, Constantinos J. Limas and Jay N. Cohn

METHODS

259 **Complications of Percutaneous Femoral Arterial Catheterization. Prospective Evaluation with the Doppler Ultrasonic Velocity Detector.** Robert W. Barnes, John L. Petersen, Richard B. Krugmire, Jr. and D. Eugene Strandness, Jr.

264 **New Instrument for Transvenous Cardiac Biopsy.** Philip K Caves, Werner P. Schulz, Eugene Dong, Jr., Edward B. Stinso and Norman E. Shumway

HISTORICAL MILESTONES

268 **Julius Cohnheim's Experiments on Heart Valves.** Saul Jarcho

PROGRESS REPORTS

271 **Principles and Pitfalls in Establishing Normal Electrocardiographic Limits.** Ernst Simonson

DIAGNOSTIC SHELF

277 **Echocardiographic Manifestations of Discrete Subaortic Stenosis.** Richard H. Davis, Harvey Feigenbaum, Sonia Chang, Lee L Konecke and James C. Dillon

281 **Echocardiographic Diagnosis of Left Atrial Myxoma.** Enrique C Martinez, Thomas D. Giles and George E. Burch

286 **Delayed Systolic Peak of the Femoral Pulse from Kinking of the Aortic Arch.** Kyuhyun Wang, Donald Harrington and Fredarick L Gobel

CASE REPORTS

291 **Demonstration of Dual Atrioventricular Nodal Pathways in Man** Kenneth M. Rosen, Ashwin Mehta and Robert A. Miller

295 **Pacemaker-Induced Cardiovascular Failure. Hemodynamic and Angiographic Observations.** John M. Haas and Gail B. Strait

300 **Double Opening Sound Related to Dysfunction in a Caged Disc Mitral Valve Prosthesis.** Earl C. Harrison, E. John Roschke, Ma sayoshi Matsuno and John W. Allen

304 **Multiple Coronary Arteriosystemic Fistulas.** Kota Reddy, Mohin der Gupta and Robert I. Hamby

EDITORIALS

307 **Ventricular Dysfunction in Coronary Artery Disease.** Peter F Cohn, Michael V. Herman and Richard Gorlin

311 **Second Degree Atrioventricular Block. A Matter of Definition.** S Serge Barold and H. David Friedberg

316 **Current Status of Circulatory Assist Devices.** Lawrence S Cohen

319 **Paul Dudley White 1886–1973. The Full Life.** E. Grey Dimond

SPECIAL DEPARTMENTS

320 **Letters to the Editor:** Echocardiogram in *d*-Transposition of Great Arteries—Glaser et al.

322 **Book Reviews**

325 **Reviews in Cardiology**

326 **College News**

CONTENTS: VOLUME 33

MARCH 1974

CLINICAL STUDIES

327 **Atropine-Induced Cardioacceleration and Myocardial Blood Flow in Subjects With and Without Coronary Artery Disease.** Suzanne B. Knoebel, Paul L. McHenry, John F. Phillips and Steven Widlansky

333 **Electrophysiologic Effects of Atropine on Atrioventricular Conduction Studied by His Bundle Electrogram.** Masood Akhtar, Anthony N. Damato, Anthony R. Caracta, William P. Batsford, Mark E. Josephson and Sun H. Lau

344 **Effects of Digoxin on Atrioventricular Conduction Patterns in Man.** Andrew C. Przybyla, Karlen L. Paulay, Emanuel Stein and Anthony N. Damato

351 **Diagnostic Value of Clinical History, Exercise Testing and Atrial Pacing in Patients with Chest Pain.** Jan Piessens, Walter van Mieghem, Hugo Kestleloot and Hilaire de Geest

357 **Pulmonary Arterial Diastolic Pressure in Acute Myocardial Infarction.** Michael Rotman, James T. T. Chen, Ronald P. Seningen, John Hawley, Galen S. Wagner, Robert M. Davidson and Marcel R. Gilbert

363 **Early Sequential Changes in Left Ventricular Dimensions and Filling Pressure in Patients After Myocardial Infarction.** McKamy Smith, Robert A. Ratshin, Frank E. Harrell, Jr., Richard O. Russell, Jr. and Charles E. Rackley

370 **Left Ventricular A Wave Amplitude in Patients After Myocardial Infarction.** McKamy Smith, Richard O. Russell, Jr., Roger E. Moraski, Bolling J. Feild and Charles E. Rackley

378 **Dynamic Characterization of Premature Ventricular Beats and Ventricular Tachycardias.** Leslie M. Eber, Barouh V. Berkovits, Jack M. Matloff, Richard Gorlin, with the technical assistance of John M. Cooke

EXPERIMENTAL STUDIES

384 **Surface Recording of Electrical Activity from the Region of the Bundle of His.** Nancy C. Flowers, R. Chris Hand, Patricia C. Orander, Carey B. Miller, Mary O. Walden and Leo G. Horan

390 **Microelectrode Study of Wenckebach Periodicity in Canine Purkinje Fibers.** James R. Wennemark and Jack P. Bandura

METHODS

399 **Detection of Ventricular Arrhythmias in Real-Time with a Portable Analog Computer.** David S. Cannom and Donald C. Harrison

PEDIATRIC CARDIOLOGY

403 **Ventricular Septal Defect with Increased Pulmonary Vascular Resistance. Late Results of Surgical Closure.** Beat Friedli, B. S. Langford Kidd, William T. Mustard and John D. Keith

410 **Effect of Red Cell Volume Reduction on Pulmonary Blood Flow in Polycythemia of Cyanotic Congenital Heart Disease.** Amnon Rosenthal and Donald C. Fyler

REPORTS ON THERAPY

415 **Bypass Graft Surgery Versus Medical Therapy of Angina Pectoris.** Wilbert S. Aronow and Edward A. Stemmer

SYMPOSIUM ON THE EFFECTS OF SURGICAL TREATMENT ON THE NATURAL HISTORY OF ACQUIRED HEART DISEASE. PART I. CORONARY ARTERY DISEASE

421 **Introduction** John Ross, Jr.

423 **Natural History of Angina Pectoris.** T. Joseph Reeves, Albert Oberman, William B. Jones and L. Thomas Sheffield

431 **Outlook for Patients After Coronary Artery Revascularization.** Vincent L. Gott

DIAGNOSTIC SHELF

438 **Echocardiographic Features of Primary Pulmonary Hypertension.** Daniel J. Goodman, Donald C. Harrison and Richard L. Popp

EDITORIALS

444 **Noninvasive Methods for Recording Bundle of His Activity.** Anthony N. Damato

446 **Preinfarction Ill Health.** Peter G. F. Nixon and Hugh J. N. Bethell

SPECIAL DEPARTMENTS

450 **Abstracts: Addendum**

453 **Book Reviews**

453 **Reviews in Cardiology**

454 **American College of Cardiology News**

CONTENTS: VOLUME 33

APRIL 1974

CLINICAL STUDIES

459 **Seattle Heart Watch: Initial Clinical, Circulatory and Electrocardiographic Responses to Maximal Exercise.** Robert A. Bruce, George O. Gey, Jr., Manuel N. Cooper, Lloyd D. Fisher and Donald R. Peterson

470 **Electrocardiogram in Acute Pericarditis. Distributions of Morphologic and Axial Changes by Stages.** David H. Spodick

475 **Posterior Wall Velocity: An Unreliable Index of Total Left Ventricular Performance in Patients with Coronary Artery Disease.** Philip Ludbrook, Joel S. Karliner, Arnold London, Kirk L. Peterson, George R. Leopold and Robert A. O'Rourke

483 **Mortality in Patients Undergoing Coronary Artery Bypass Surgery After Myocardial Infarction.** John T. Dawson, Robert J. Hall, Grady L. Hallman and Denton A. Cooley

487 **Lidocaine-Induced Heart Block in Patients with Bundle Branch Block.** Prem K. Gupta, Edgar Lichstein and Kul D. Chadda

493 **Improved Intraventricular Conduction of Premature Beats After Diphenylhydantoin.** Joe K. Bissett, Neil D. B. de Soyza, James J. Kane and Marvin L. Murphy

498 **Effect of Glucose-Insulin-Potassium Infusion on the Human Conduction System.** Lawrence Gould, C. V. Reddy and Robert F. Gomprecht

507 **Effect of Glucagon on Cardiac Conduction in Man.** Ramesh C. Dhingra, Ashfaque Khan, Delon Wu, Pablo Denes, J. Maurice Pouget and Kenneth M. Rosen

EXPERIMENTAL STUDIES

513 **Beneficial Electrophysiologic Effects of Nitroglycerin During Acute Myocardial Infarction.** Kenneth M. Kent, Eldon R. Smith, David R. Redwood and Stephen E. Epstein

517 **Nitroglycerin-Induced Reduction in the Incidence of Spontaneous Ventricular Fibrillation During Coronary Occlusion in Dogs.** Jeffrey S. Borer, Kenneth M. Kent, Robert E. Goldstein and Stephen E. Epstein

521 **Modification of Experimental Myocardial Infarct Size by Cardiac Drugs.** Pritpal S. Puri

529 **Pathophysiology of Tachycardia- and Bradycardia-Dependent Block in the Canine Proximal His-Purkinje System After Acute Myocardial Ischemia.** Nabil El-Sherif, Benjamin J. Scherlag, Ralph Lazarra and Philip Samet

METHODS

541 **Blood Flow Velocity Measured at the Mitral Valve of Man.** Kenneth B. Desser and Alberto Benchimol

REPORTS ON THERAPY

546 **Large Dose Furosemide Therapy for Hypertension. Long-Term Use in 22 Patients.** William J. Mroczek, Michael Davidov and Frank A. Finnerty, Jr.

HISTORICAL MILESTONES

550 **Experiments on the Mitral Valve (Stricker, 1883).** Saul Jarcho

CASE REPORTS

553 **Paroxysmal Atrioventricular Block Related to Phase 4-Bilateral Bundle Branch Block.** Gianni Corrado, Raul J. Levi, Gerardo J. Nau and Mauricio B. Rosenbaum

557 **Aneurysm of the Left Atrium.** Thomas J. Hougen, Donald G. Mulder, Michael T. Gyepes and Arthur J. Moss

562 **Acute Dissecting Aortic Aneurysm Resulting from Retrograde Brachial Arterial Catheterization. Successful Operative Intervention.** Harry A. Wellons, Jr. and Rajindar Singh

566 **Successful Total Repair of Interrupted Aortic Arch Associated with Ventricular Septal Defect and Large Patent Ductus Arteriosus.** Jacques G. Losman, Hymie S. Joffe, Walter Beck and Christiaan Barnard

SPECIAL DEPARTMENTS

572 **Letters to the Editor:** Heart Rate in Acute Myocardial Infarction—Sarnoff • Academic vs. Community Surgeons—Hudson

574 **Reviews in Cardiology**

576 **American College of Cardiology News**

CONTENTS: VOLUME 33

MAY 6, 1974

CLINICAL STUDIES

583 **Bundle Branch Block. Demonstration of the Incomplete Nature of Some "Complete" Bundle Branch and Fascicular Blocks by the Extrastimulus Technique.** Delon Wu, Pablo Denes, Ramesh Dhingra and Kenneth M. Rosen

590 **Concealed Bypasses of the Atrioventricular Node in Patients with Paroxysmal Supraventricular Tachycardia Revealed by Intracardiac Stimulation and Verapamil.** Roworth A. J. Spurrell, Dennis M. Krikler and Edgar Sowton

596 **Electrophysiologic Properties of Procainamide in Man.** Mark E. Josephson, Anthony R. Caracta, Michael A. Ricciutti, Sun H. Lau and Anthony N. Damato

604 **Arrhythmias After Cardiac Transplantation.** John S. Schroeder, David K. Berke, Anthony F. Graham, Alan K. Rider and Donald C. Harrison

608 **Criteria for Electrocardiographic Differentiation of Right Ventricular Hypertrophy from True Posterior Myocardial Infarction.** P. Manohar Kini and Hubert V. Pipberger

614 **Comparative Prevalence of the Fourth Heart Sound in Hypertensive and Matched Normal Persons.** Michael Swistak, Harry Mushlin and David H. Spodick

EXPERIMENTAL STUDIES

617 **Sinus Nodal Reentry. Effect of Quinidine.** Karlen L. Paulay, Gerald M. Weisfogel and Anthony N. Damato

623 **Functional Anatomy of the Canine Left Bundle Branch.** Philip Lazzara, Billy K. Yeh and Philip Samet

633 **Electrophysiologic Antagonism of Quinidine and Bretylium Tosylate.** Irany M. De Azevedo, Yoshio Watanabe and Leonard S. Dreifus

639 **Effects of Intraperitoneal Administration of Propranolol on the Mouse Heart. Histochemical and Electron Microscopic Observations.** Edgar F. Allin, Janice M. Miller, George G. Rowe and James A. Will

METHODS

643 **Computerized System for Noninvasive Techniques. I. Its Value for Systolic Time Intervals.** Samuel Zoneraich, Olga Zoneraich and John Rodenrys

650 **Quantification of Serum Creatine Phosphokinase Isoenzyme Activity.** Robert Roberts, Philip D. Henry, Sake A. G. J. Witteeveen and Burton E. Sobel

REPORTS ON THERAPY

655 **Prophylactic Quinidine for the Prevention of Arrhythmias After Acute Myocardial Infarction.** David T. Jones, William J. Kostuk and Ramsay W. Gunton

661 **Comprehensive Treatment Plan for the Prevention of Primary Ventricular Fibrillation in Acute Myocardial Infarction.** Milford G. Wyman and Lucille Hammersmith

PEDIATRIC CARDIOLOGY

668 **Ostium Secundum Atrial Septal Defect Associated with Balloon Mitral Valve in Children.** Benjamin E. Victorica, Larry P. Elliott and Ira H. Gessner

674 **Cyanosis in Patients with Atrial Septal Defect Due to Systemic Venous Drainage into the Left Atrium.** Maxwell S. Maillis, Tsung O. Cheng, Jerry F. Meyer, I. Sylvia Crawley and Joseph Lindsay, Jr.

SYMPOSIUM ON EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE

Ezra A. Amsterdam, Jack H. Wilmore and Anthony N. DeMaria, *Guest Editors*

713 **Introduction**

715 **Methods of Exercise Testing. Step Test, Bicycle, Treadmill, Isometrics.** Robert A. Bruce

721 **Exercise Electrocardiography: Recognition of the Ischemic Response, False Positive and Negative Patterns.** Albert A. Kattus

732 **Disturbances of Cardiac Rhythm and Conduction Induced by Exercise. Diagnostic, Prognostic and Therapeutic Implications.** Anthony N. DeMaria, Zakauddin Vera, Ezra A. Amsterdam, Dean T. Mason and Rashid A. Massumi

737 **Indirect Assessment of Myocardial Oxygen Consumption in the Evaluation of Mechanisms and Therapy of Angina Pectoris.** Ezra A. Amsterdam, James L. Hughes, III, Anthony N. DeMaria, Robert Zelis and Dean T. Mason.

744 **Experimental Observations on the Effects of Physical Training Upon Intrinsic Cardiac Physiology and Biochemistry.** James Scheuer, Somsong Penpargkul and Ashok K. Bhan

752 **Medical Screening of Patients with Coronary Artery Disease. Criteria for Entrance into Exercise Conditioning Programs.** Malcolm M. McHenry

757 **Individual Exercise Prescription.** Jack H. Wilmore

760 **Effects of Physical Training on Coronary Risk Factors.** Joseph A. Bonanno and James E. Lies

765 **Long-Term Physiologic Adaptations to Exercise with Special Reference to Performance and Cardiorespiratory Function in Health and Disease.** William C. Adams, Malcolm M. McHenry and Edmund C. Bernauer

776 **Physical Activity After Myocardial Infarction.** William L. Haskell

784 **Coronary Heart Disease as a Pediatric Problem. Prevention Through Behavior Modification.** John L. Boyer

787 **Physical Fitness Programs for Adults.** Karl G. Stoedefalke

END OF SYMPOSIUM

CLINICAL STUDIES

791 **Comparative Response to Isometric (Static) and Dynamic Exercise Tests in Coronary Disease.** Jean-Claude Haissly, Roger Messin, Serge Degre, Pol Vandermoten, Betty Demaret and Henri Denolin

797 **Comparison of the Two-Step and Maximal Exercise Tests in Patients with Coronary Artery Disease.** Paul Schweitzer, V. Michael Jelinek, Michael V. Herman and Richard Gorlin

801 **Arm-Crank Ergometry: A New Method for the Evaluation of Coronary Artery Disease.** David J. Shaw, Michael H. Crawford, Joel S. Karliner, George DiDonna, Richard M. Carleton, John Ross, Jr. and Robert A. O'Rourke

806 **Effects of Perhexiline on Symptomatic and Hemodynamic Responses to Exercise in Patients with Angina Pectoris.** Carl J. Pepine, Steven J. Schang and Carl R. Bemiller

813 **Myocardial Infarction After Exercise-Induced Electrocardiographic Changes in a Patient with Variant Angina Pectoris.** R. Leldon Sweet and L. Thomas Sheffield

CONTENTS: VOLUME 33

JUNE 1974

CLINICAL STUDIES

819 **Hemodynamic Effects of Noninvasive Systolic Unloading (Nitroprusside) and Diastolic Augmentation (External Counterpulsation) in Patients with Acute Myocardial Infarction.** William W. Parmley, Kanu Chatterjee, Yzhar Charuzi and H. J. C. Swan

826 **Prognostic Indexes in Acute Myocardial Infarction Complicated by Shock.** Abdelmonen A. Afifi, Potter C. Chang, Vinnie Y. Liu, Protasio L. da Luz, Max Harry Weil and Herbert Shubin

833 **Mechanism and Significance of Widened QRS Complexes During Complete Atrioventricular Block in Acute Inferior Myocardial Infarction.** K. I. Lie, Hein J. Wellons, Reinier M. Schuilenburg and Dirk Durrer

840 **Platelet Survival in Patients with Prosthetic Heart Valves.** R. Kenneth Stuart, John W. McDonald, Suraj P. Ahuja and John C. Coles

EXPERIMENTAL STUDIES

845 **Encephalogenic Cardiomyopathy After Stimulation of the Brain Stem in Monkeys.** Hsing I. Chen, Shih Chien Sun, Chok Yung Chai, Shih Liang Kau and Chien Kou

853 **Reflex Inhibitory Effects of Vagal Afferents in Experimental Myocardial Infarction.** Paul Kezdi, R. Karl Kordenat and Sarda N. Misra

861 **Accumulation of Gallium-67 in Regions of Acute Myocardial Infarction.** Robert J. Kramer, Robert E. Goldstein, John W. Hirshfeld, Jr., William C. Roberts, Gerald S. Johnston and Stephen E. Epstein

868 **Dimensional Changes of the Left Ventricle During Acute Pulmonary Arterial Hypertension in Dogs.** Edward W. Stool, Charles B. Mullins, Stephen J. Leshin and Jere H. Mitchell

876 **Ventricular Conduction Delay and Asystole During Systemic Hyperkalemia.** Philip O. Ettinger, Timothy J. Regan, Henry A. Oldewurtel and Mohammad I. Khan

METHODS

887 **Permanent Pervenous Transseptal Atrial Pacing. Canine Experiments and a Clinical Case.** John A. Udall

PEDIATRIC CARDIOLOGY

892 **Evaluation of Patients with Pulmonary Atresia and Intact Ventricular Septum by Double Catheter Technique.** Robert M. Freedom, Robert I. White, Jr., Charles S. Ho, Robert L. Gingell, Richard E. Hawker and Richard D. Rowe

896 **Echocardiographic Assessment of Cardiac Malposition.** Richard A. Meyer, David C. Schwartz, Wesley Covitz and Samuel Kaplan

HISTORICAL MILESTONES

904 **Experimental Mitral Insufficiency (Bettelheim and Kauders).** Saul Jarcho

CASE REPORTS

908 **Tachycardia-Dependent and Bradycardia-Dependent Mobitz Type II Atrioventricular Block Within the Bundle of His.** Michael A. Goodfriend and S. Serge Barold

914 **Mitral and Tricuspid Lesions Associated with Polypoid Atrial Tumors, Including Myxoma.** John B. Carter, Ralph Cramer, Jr. and Jesse E. Edwards

920 **Caseating Granulomas of the Heart.** T. Sterling Claiborne

924 **Emergency Thrombectomy for Acute Coronary Bypass Graft Occlusion.** J. Edward Okies and Richard P. Anderson

EDITORIALS

why settle for less

THAN A COMPLETE CARDIAC DIAGNOSTIC SYSTEM?

Why indeed! Medcraft's CDC 70 System is a real workhorse. Use it.

- *for stress testing*
- *as an ambulatory patient monitor*
- *for routine office ECG's.*

Doesn't it make a lot of good sense to have *one* sophisticated, yet rugged instrument for all your cardiac testing needs. A Cardiac Diagnostic System that is versatile enough to be kept in use all day? The all solid-state CDC 70, Cardiac Diagnostic System, is easy to use, compact, and smartly styled. It offers a memory scope display and tracing printout for ECG . . . digital heart rate display . . . low-cost ambulatory patient monitoring recorders with *cassette* tape recording (up to 16 hours per cassette) . . . switchable 5-lead resting or stress test ECG . . . and a host of other wanted features and optional capabilities.

To learn more, call, write, or use the coupon below to receive our latest brochure describing the CDC 70 System. You'll be surprised at the sophisticated, years-ahead design and the low cost of owning

THE CDC SERIES 70 SYSTEM by Hittman Medcraft

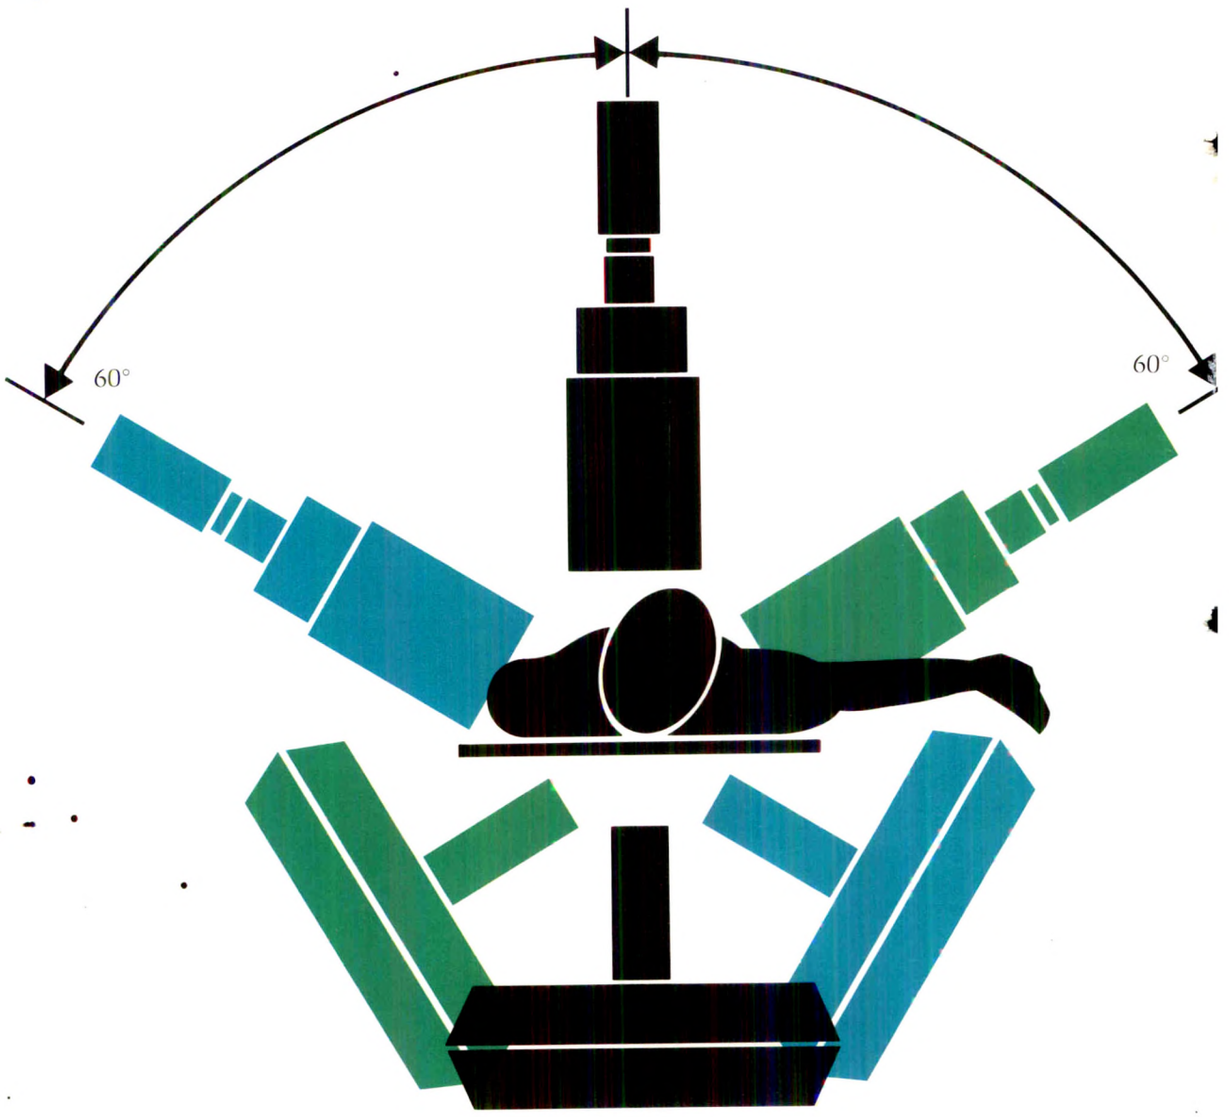
Philips



Cardio Diagnost Makes A Great U-Turn.

Cardiac angiography *can* be performed by rotating the x-ray beam around the patient – while *he* remains comfortably stationary.

What it takes is a perfect U-turn. And a rotating U-arm. In short, it takes Philips' Cardio Diagnost, designed to let you do cardiac angiography more efficiently and conveniently than ever before. A stationary patient helps make that possible.

So does simple, smoothly effected scanning. You can scan close to the chest wall in any patient plane – with just one hand. In every plane, at every turn, Philips' image quality is the finest possible.

The Cardio Diagnost also offers a startling improvement in patient handling. The examination table – actually a mobile cart – provides a built-in patient transfer system!

For a safe, efficient U-turn, especially in heavy patient traffic, consider Philips' Cardio Diagnost. It's unique in cardiac angiography. Write us for details.

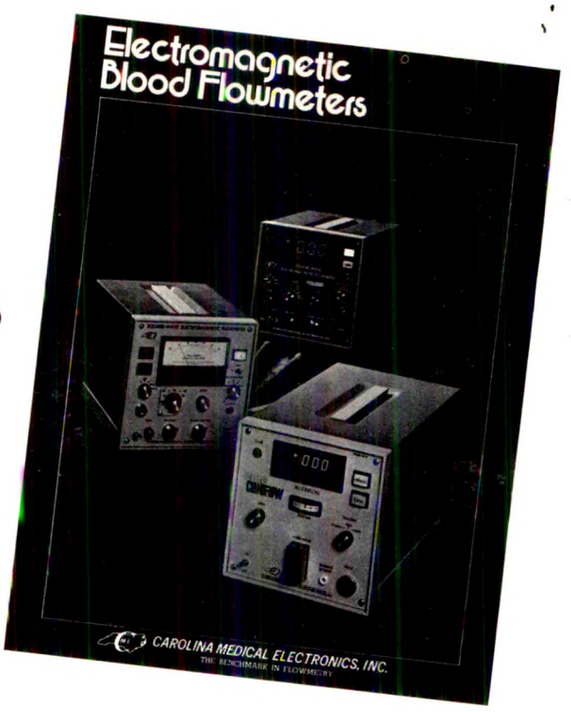
the most advanced blood flowmeters available!



What's so great about CME Flowmeters?

•Convenient Readout •Patient Safeguard System •Zero Flow Reference •Multiple Flow Adaptability •Excellent Frequency Response •Low Noise — High Resolution •Compact Size •Widest Range of Blood Flow Probes •Total System Compatibility •Comprehensive Performance in Clinical, Laboratory and Research Applications

Write or call for complete information.

BLOOD FLOW

for clinical applications

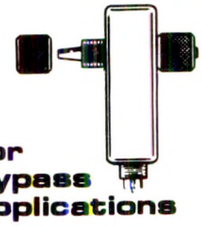
- Designed for clinical O.R. or cath lab use
- Easily applied handle-type probe
- Patient safety assured through isolation circuitry
- Simple to operate - minimum controls - direct meter readout in milliliters per minute

FLOW PROBES

for clinical applications

- Convenient, handle-type probe with positive capture slide
- Designed for O.R. and cath lab use
- For rapid analysis of flow through exposed blood vessels
- Use with Biotronex clinical blood flowmeter

FLOW PROBES



for bypass applications

- Use with heart-lung machine, artificial kidney or similar systems
- Iron core construction provides high sensitivity and accuracy
- Operates with BLI research and clinical blood flowmeters
- Available in sizes to fit most tubing

MUSE... THE QUINTESSENCE IN ECG ANALYSIS SYSTEMS

MUSE, the Marquette Universal System for Electrocardiography, provides your hospital with the capability of automating ECG readings through the use of a compact digital computer. MUSE offers the most technologically advanced programs in ECG computer analysis, including the new Smith / Mayo, IBM / Bonner, Pipberger / VA and the latest U.P.H.S. version ECAN-E. This new concept can cost justify itself by any hospital processing as few as 500 ECG's per month. The MUSE is a system of total program flexibility, simplicity of operation and protection against technological obsolesence.

For a full color brochure on this comprehensive new system, write: Marquette Electronics, Inc., Box 126, 8200 West Tower Avenue, Milwaukee, Wisconsin 53223.

"The drug of choice for oral replacement of potassium is potassium chloride solution."

AMA Drug Evaluations 1971, First Edition, Chicago, American Medical Association, p. 121.

Kay Ciel® Elixir is potassium chloride... tastes good too!

COMPOSITION: Each 15 cc. (one tablespoonful) contains potassium chloride 1.5 Gm., supplying 20 mEq. of elemental potassium, in a cherry-flavored, palatable base, alcohol 4%. Contains no sugar.
INDICATIONS: Treatment of potassium deficiency occurring especially during thiazide diuretic or corticosteroid therapy, digitalis intoxication, low dietary intake of potassium or as a result of excessive vomiting and diarrhea.
CONTRAINDICATIONS: Impaired renal function, untreated Addison's Disease, dehydration, heat cramps, and hyperkalemia.
PRECAUTIONS: Potassium chloride should be administered with caution and adjusted to the requirements of the individual patient, since the amount of deficiency and corresponding daily dose is often not known. Excessive or even therapeutic dosages may result in potassium intoxication. Patients should be frequently checked and periodic ECG and/or plasma potassium levels made. High plasma concentrations of potassium ion may cause cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease. In hypokalemic states, attention should be directed toward the correction of the frequently associated hypochloremic alkalosis.
SIDE EFFECTS: Vomiting, nausea, abdominal discomfort and diarrhea may occur. Symptoms and signs of potassium intoxication include listlessness, mental confusion, paresthesia of the extremities, weakness of the legs, flaccid paralysis, fall in blood pressure, cardiac arrhythmias, and heart block. When hyperkalemia exists, it should be promptly treated with the discontinuance of potassium administration or other steps to lower serum levels if indicated, since sudden shift in plasma levels may induce potentially dangerous cardiac arrhythmias.
DOSAGE AND ADMINISTRATION: Adults, one tablespoonful (15 cc.) diluted in one glass of water, twice daily after the morning and evening meal. Larger doses may be indicated according to the individual patient's requirements but should be administered under close supervision due to the possibility of potassium intoxication. Patients should be cautioned to follow directions explicitly in regard to dilution of Kay Ciel Elixir to prevent gastrointestinal injury.
HOW SUPPLIED: One pint and one gallon bottles.

Cooper Cooper Laboratories, Inc., Wayne, N.J. 07470/Ste. Therese, P.Q., Canada
